Parkinson’s disease (PD) is a common neurodegenerative disorder with a variety of motor and non-motor features. Non-motor symptoms, such as gastrointestinal dysfunction, usually set in 5 to 15 years earlier than motor manifestations. Cytoplasmic aggregates of phosphorylated α-synuclein are a typical marker of PD. They are observed not only in cerebral neurons but also in intramural plexuses of the intestine. Therefore, it is essential to investigate the peripheral component of the molecular pathogenesis of the disease using PD models, including those involving the use of parkinsonian neurotoxins, such as the well-known herbicide paraquat. The aim of this study was to identify a complex of early α-synuclein-related changes induced by long-term systemic administration of paraquat to rats at doses of 6 mg/kg. The open-field test revealed a decline in the motor activity of the experimental animals; the tapered beam walking test demonstrated a two-fold increase (p = 0.044) in the number of left paw slips. Besides, the intensity of staining for tyrosine hydroxylase (TH) in the substantia nigra and myenteric plexus fibers was 50% (p = 0.033) and 20% (p = 0.01) lower, respectively, in the main group than in the controls. Phosphorylated α-synuclein content was increased in the cell bodies of myenteric neurons and in TH-positive nervous fibers of the experimental animals. Changes indicating the development of peripheral α-synuclein pathology in the early stage of induced PD are similar to the changes observed in patients with PD at the onset of the disease. The proposed paraquat regimen could be very promising for PD modeling.

Keywords: Parkinson’s disease, animal models, α-synuclein, paraquat, behavior, tyrosine hydroxylase

Funding: this work supported by the Russian Science Foundation (Grant 19-15-00328).

Acknowledgement: the authors thank their colleagues, Olshtansky AS and Yamshchikova NG (the Laboratory of Experimental Pathology of the Nervous System), for their valuable contribution.

Author contribution: Stavrovskaya AV planned the study, analyzed the literature, collected, analyzed and interpreted the obtained data, conducted behavioral tests, administered drugs to the animals, and prepared the draft of the manuscript; Voronkov DN analyzed the literature, analyzed and interpreted the obtained data, prepared brain slides, conducted the histopathologic examination, and prepared the draft of the manuscript; Kutukova KA analyzed the literature, analyzed the obtained data, prepared jejunum slides, carried out the histo-pathologic examination, and prepared the draft of the manuscript; Ivanov MV prepared jejunal slides and carried out the histopathologic examination; Gushchina AS collected data, administered drugs to the rats, carried out behavioral tests, and monitored the animals’ health as a vet; Illarioshkin SN supervised the study and prepared the draft of the manuscript.

Compliance with ethical standards: the animals were treated and the experiments were conducted in full compliance with the Guide for the Care and Use of Laboratory Animals; the study was approved by the Ethics Committee of Research Center of Neurology (Protocol № 2–5/19 dated February 20, 2019).

PARAKVATNAYA MODEL’ PARKINSONIZMA I BYAVLENIE FOSFORILIROVANNOGO α-SYNKLEININA V ENTERAL’NOY NERVNOY SISTEME U KRYUS

Болезнь Паркинсона (БП) — распространенное нейродегенеративное заболевание с широким спектром моторных и немоторных нарушений. Немоторные симптомы (в частности, нарушения функции желудочно-кишечного тракта) обычно опережают манифестацию нарушений моторики на 5–15 лет. Характерные признаки БП, цитоплазматические агрегаты фосфорилированного белка α-синуклеина, обнаруживают не только в церебральных нейронах, но и в интраузральных вегетативных сплетениях кишечника. В связи с этим большое значение имеет оценка периферического звена молекулярного патогенеза БП на экспериментальных моделях, в том числе при воздействии специфических «паркинсонических» нейротоксинов, таких как гербицид параquat.

Целью работы было выявить комплекс ранних патологических изменений, возникающих при использовании α-синуклеин, при системном многократном введении крысам параquat в дозе 6 мг/кг. У экспериментальных животных было показано снижение двигательной активности в открытой поле, двукратное (p = 0,044) одностороннее увеличение числа случаев соскальзывания в тесте «сужающаяся дорожка», снижение интенсивности окрашивания на тирозингидроксилазу (TH) в субстанция нигра и миентеральное сплетение кишечника крысы на 50% (p = 0,033) и на 20% (p = 0,01) соответственно, а также увеличение содержания фосфорилированного α-синуклеина в телах миентеральных нейропетали и в ТирГ-позитивных волокнах. Полученные изменения, свидетельствующие о развитии периферической α-синуклеинопатии на ранней стадии экспериментального паркинсонизма, сходны с таковыми у пациентов в дебюте БП. Предложенный режим введения параquatа может быть чрезвычайно перспективным в моделировании БП.

Ключевые слова: болезнь Паркинсона, моделирование на животных, α-синуклеин, параquat, поведение, тирозингидроксилаза

Благодарности: авторы благодарят сотрудников лаборатории экспериментальной патологии нервной системы А. С. Ольшанского и Н. Г. Ямщикову за их помощь в работе.

Parkinson’s disease (PD) is a widespread neurological disorder most common in people over > 60 years of age. It is estimated that at least 4 million individuals are affected worldwide. Today, the world’s population is aging, and PD prevalence is expected to double by 2040 [1]. In the absence of curative treatment, the focus should be placed on researching the underlying molecular mechanisms of PD in animal models.

Typical motor symptoms of PD (bradykinesia, rigidity, resting tremors) are linked to the loss of dopaminergic neurons in substantia nigra pars compacta, nigrostriatal pathway degeneration and progressive neurotransmitter imbalance in the central nervous system (CNS) [2]. Non-motor features constitute of motor symptoms. This study aimed to identify a complex of prodromal PD or to assess non-motor symptoms that precede the onset of motor symptoms are manifested [3]. Although the peripheral nervous system (PNS) is thought to be implicated in PD-related gastrointestinal dysfunction, its trigger mechanisms and patterns of interaction between the CNS and PNS contributors to PD pathogenesis have not been completely elucidated.

The most significant molecular event leading to the loss of CNS neurons in patients with PD is misfolding of a small synaptic protein known as α-synuclein [4]. Phosphorylated α-synuclein aggregates observed in the neuronal cytoplasm are the primary constituents of Lewy bodies — the classic histopathological hallmarks of PD [2]. Interestingly, α-synuclein pathology is not confined to cerebral neurons and is also seen in biopsy and autopsy specimens of the intramural intestinal plexus obtained from patients with PD. This inspired a hypothesis that the disease begins in enteric plexuses and then spreads to other CNS structures via the vagus nerve [5]. Some findings suggest that the α-synuclein cascade is triggered by certain environmental neurotoxins, such as heavy metals, pesticides and fungicides [6, 7]. For example, abnormal α-synuclein aggregation can be induced by the powerful non-selective herbicide paraquat (1,1-dimethyl-4,4-bipyridinium dichloride). Paraquat is widely used for controlling noxious weeds that invade orchards, agricultural lands, coffee, tea and cocoa plantations, as well as for desiccating crops [6, 8, 9]. It bears structural resemblance to 1-methyl-4-phenylpyridinium (MPP+), the toxic metabolite of the well-known neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). This makes paraquat suitable for modeling PD in animals. The toxic effect of paraquat is linked to the production of superoxide radicals; at the same time, paraquat is insensitive to the intramural intestinal plexus obtained from patients with PD.

Studies exploiting animal models of PD usually involve long-term exposure to paraquat administered systemically at 10 mg/kg. Such regimens result in pronounced motor impairment in the animals and cause significant degeneration of dopaminergic neurons in the substantia nigra [10]. This approach cannot be applied to obtain information about the early stages of PD or to assess non-motor symptoms that precede the onset of motor impairment. This study aimed to identify a complex of prodromal α-synuclein-related pathological changes in rats exposed to small doses of paraquat and to compare it to the symptoms observed in the experimental animals in the early stage of induced PD.

METHODS

The study was conducted in male Wistar rats (n = 18) aged 3-3.5 months. The animals were kept under standard housing conditions (the 12/12 light/dark cycle) and had free access to food and water.

The animals were stratified into the main (paraquat) group (n = 10) and the control group (n = 8). Paraquat was dissolved in normal saline; 0.5 ml (6 mg/kg) of the obtained solution were administered to the animals from the main group on alternate days over the course of 4 weeks. The control group received an equal amount of normal saline. The next day after the last injection, the open field test (OPT) and the tapered beam walking test (BWWT) were conducted to assess locomotor activity in the animals. The initial level of motor activity was measured in intact rats before the experiment. The open field arena was fabricated in the workshop of Research Institute of Neurology. It was a cube-shaped 75 x 75 x 40 cm box; its floor was divided into 25 equal squares. During the open-field test, we measured the distance each rat covered within 3 minutes. The beam-walking apparatus (open beam) for each animal was made of 2 carpentry 165 cm-long beams; the bottom beam was 10 to 5.5 cm in width; the lower beam, 6 to 1.5 cm; the height was 2 cm for both beams. The enclosure at the narrow end of the walking bridge had a removable lid and a hole in the front panel to allow the animal inside. The apparatus was installed 70 cm above the floor. The rat traveled along the top beam from its far end towards the safe enclosure. For each animal, we counted the number of slips from the top beam throughout the entire route and the total number of steps made by each paw. The experiment was recorded using the Any-maze video-tracking system (Stoelting Inc.; USA).

Four brain tissue samples were selected from each group for further histopathologic examination. Briefly, the brain was removed and fixed in 4% formalin. The samples were soaked in O.C.T. compound (TissueTek; USA); a series of 10-μm frontal sections was prepared in a Tissue-Tek Cryo3 Flex cryostat (Sakura Finetek; USA). The slides were immunofluorescently stained in order to determine tyrosine hydroxylase (TH) and glial fibrillary acidic protein (GFAP) content in the tissue. TH is a marker for dopaminergic neurons, while GFAP is a protein whose expression is indicative of neurodegeneration in the nigrostriatal system. Cell nuclei were stained with DAPI. TH content was determined using polyclonal rabbit antibodies (1 : 500, Sigma; Germany) and CF488-conjugated goat secondary anti-rabbit antibodies (1 : 500, Sigma; Germany). GFAP levels were estimated using Cy3-conjugated antibodies (1 : 80; Sigma). We examined 5 to 10 slides of each brain sample prepared from the tissue along the rostrocaudal axis at the level of the caudate nuclei and substantia nigra. The slides were studied under the Eclipse NIU fluorescence microscope (Nikon; Japan). The density of TH-positive fibers was estimated in manually delineated regions at ×40 magnification in ImageJ (Wayne Rasband NIH; USA); the mean fluorescence intensity of striatal tissue was corrected to background fluorescence.

Five to seven cm-long regions of the jejunum were excised and dissected in the longitudinal plane following the mesentery course, washed in normal saline and spread out on the paraflin-coated bottom of Petri dishes. The specimens were fixed in 4% buffered formalin for 3 h and then washed in a phosphate buffer (pH = 7.4). After that, the mucosal lining and the underlying submucosal layer were removed with ophthalmic forceps; the procedure was carried out under the Wild M7A stereomicroscope (Wild Heerbrugg; Germany). Fluorescence assays were performed on the obtained samples of the jejunum constituted of circular and longitudinal muscle fibers and the myenteric plexus. Primary antibodies to class III β-tubulin, TH and serin-129-phosphorylated α-synuclein (α-Syn-p129) taken at 1 : 250 dilutions were used to identify nervous fibers in the myenteric plexus. Visualization of binding reactions was aided by secondary CF448-conjugated antibodies (Sigma; Germany) taken at a 1 : 100 dilution. The samples were examined and photographed using Nikon Eclipse NIU (Nikon; Japan)
equipped with a Nikon DS-Qi digital camera (Nikon; Japan). Morphometric measurements were done in NIS Elements (Nikon; Japan) using images obtained at ×10 magnification in at least 30–40 fields of view per animal. The mean fluorescence intensity and brightness (corrected to background staining) of the myenteric plexus fibers positive for class III β-tubulin and TH were measured in the NIS Elements software.

The obtained data were analyzed in Statistica 12 (StatSoft; USA); one-way ANOVA was followed by Fisher’s exact test and Mann-Whitney U test for post-hoc comparisons. The differences were considered significant at $p < 0.05$.

RESULTS

Each experimental animal received a total of 12 paraquat injections. The initial distance travelled by the intact rats in the open field was 4.96 ± 0.7 m. The next day after the last injection, OFT revealed a decline in motor activity in the rats who had been exposed to paraquat, but the differences between the groups were insignificant (Fig. 1).

BWT demonstrated poor motor coordination in the rats from the main group manifesting itself as a statistically significant increase in the number of slips from the top beam made by left paws (Fig. 2). The number of slips was expressed as percentage from the total number of steps made by the corresponding limb.

The intensity of staining for TH was decreased in the substantia nigra of the animals who had been receiving paraquat injections; the histopathologic examination revealed damage to dopaminergic neurons. The most pronounced changes were observed in the striatum. The intensity of TH-positive staining in striatal tissue was significantly lower in the main group than in the controls (Fig. 3). Low density of the detected dopaminergic fibers was predominantly observed in the dorsal aspect of the striatum. Another important finding was moderate gliosis (hypertrophy of GFAP-positive astrocyte projections).
The intensities of staining for class III β-tubulin and TH were low in the myenteric plexus of the rat jejunum (Fig. 4). The levels of phosphorylated α-synuclein (α-Syn-p129) were elevated in the cell bodies of myenteric neurons and in TH-positive fibers (Fig. 5).

**DISCUSSION**

Paraquat holds great promise for PD modeling; some of its properties make paraquat-induced PD models suitable for exploring hypotheses of PD pathogenesis and testing novel drugs [11]. According to the literature, paraquat induces neuronal stress, stimulates production of free radicals in vitro and in vivo, causes elevation of α-synuclein and tau, and promotes deposition of these proteins [8, 12, 13]. Despite the structural similarity between paraquat and MPP⁺ [14], the two neurotoxins enter the brain via different pathways and have different mechanisms of action. Both of them are charged molecules; however, unlike MPP⁺, paraquat is delivered to the brain by a neutral amino acid transporter [15, 16]. Reports of paraquat effects on dopaminergic neurons are controversial. Some authors describe motor dysfunction and death of dopaminergic neurons in rats and mice following systemic administration of paraquat [14, 10, 17]. Others report that experimental animals show no signs of motor deterioration in spite of nigrostriatal pathway degeneration [18, 14]. Although paraquat induces aggregation of α-synuclein and other damage to dopamine-producing neurons of the substantia nigra, it does not have a pronounced effect on dopamine levels in the striatum, which might be due to the compensatory increase in TH activity in this brain region [19].

In rats, paraquat-induced PD is usually modeled by exposing the animals to 10 mg/kg doses of the herbicide dissolved in normal saline. When administered intraperitoneally for 3 weeks, such doses cause selective death of dopaminergic neurons in the substantia nigra, poor motor coordination, reduced muscle tone and contractility [10]. Higher paraquat doses (20–25 mg/kg) are used to model severe damage to internal organs, such as kidneys or lungs [20]. However, our previous experience of exposing Wistar rats to 10 mg/kg paraquat doses for modeling PD was negative: by the time of the 5th injection, all experimental animals (n = 10) had been already dead. Necropsy revealed...
tissue fibers of both experimental and control groups. Under normal conditions, some α-synuclein was detected in the peripheral nervous system. The studied brain samples were devoid of TH-containing neurons in patients with PD [22, 21]. There is also only a scarce description of PD models that recreate motor asymmetry following systemic administration of neurotoxins. Our study fills this gap.

The intensity of staining in the myenteric fibers positive for class III β-tubulin were lower in the main group than in the controls. Although paraquat-induced disruption of microtubule assembly was described previously [23], our data on decreased staining intensity in the fibers positive for class III β-tubulin are inconsistent with the results obtained by some other researchers [6]. Perhaps, our findings do not so much indicate a decline in the absolute number of tubulin-positive nervous fibers, but instead point to a changed morphology of the enteric innervation, i.e. its exhaustion.

The studied brain samples were devoid of TH-containing neuronal bodies; this suggests that TH-positive nervous fibers found in the intermuscular plexus are sympathetic afferents, which is consistent with the reports by other researchers [24, 25]. The intensity of staining for TH was lower in the paraquat group than in the controls, which may indicate damage to sympathetic innervation in the small intestine and low TH content in sympathetic nerve fibers. Weak staining intensity may reflect changes in fiber density or the functional state of the neurons.

Alpha-synuclein was detected in the peripheral nervous tissue fibers of both experimental and control groups. Under normal conditions, some α-synuclein is present in neurons in the phosphorylated state [26]. In our study, the protein was diffusely distributed in the cell bodies of some myenteric plexus neurons. At the same time, the intensity of neuronal body staining was increased and TH-containing fibers immunopositive for phosphorylated α-synuclein (α-Syn-p129) were thicker in the animals from the paraquat group. Morphological changes observed in nervous fibers and α-Syn-p129 accumulation may be indicative of paraquat-induced production of protein aggregates typically seen in PD. Our findings coupled with previous reports of paraquat-induced α-synuclein overexpression in the substantia nigra [6] emphasize the similarity of molecular pathogenesis of our PD model to the mechanisms of the actual disease.

The possible causes underlying paraquat-induced α-synuclein accumulation in the enteric nervous system include production of reactive oxygen species and inflammation [27]. It was shown previously that inflammatory disorders of the intestine trigger accumulation of phosphorylated α-synuclein in the myenteric plexus neurons of primates [28]. Imbalance between the phosphorylated and non-phosphorylated α-synuclein pools is accompanied by the production of toxic protein fibrils and formation of its insoluble aggregates [29]. Pathologic accumulation of α-synuclein in the fibers innervating the gastrointestinal tract and in the enteric plexus is typical of early PD stages and is regarded as a potential biomarker of the disease [30].

CONCLUSIONS

Systemic administration of 6 mg/kg doses of paraquat to rats induces behavioral and morphological changes similar to those seen in patients with early stages of PD, one of them being α-synuclein pathology in the peripheral nervous system that plays a key role in the pathogenesis of the disease. The proposed regimen is very promising for PD modeling and plays an important role in broadening our understanding of PD pathogenesis and developing novel therapeutic strategies.
