The spread of cancer cells throughout the body from the primary tumor occurs through the biofluids, such as blood and lymph [1]. Axillary lymph node dissection and sentinel lymph node biopsy make it possible to detect the onset of regional lymph nodes metastasis with 100% accuracy. However, the risk of complications associated with the build-up of lymph in the tissues is high due to high invasiveness of the procedures [2, 3]. The noninvasive techniques for diagnosis of regional metastasis are as follows: ultrasound, magnetic resonance imaging and positron emission tomography (MRI and PET). Ultrasound imaging is a standard technique used to search for the regional lymph node metastases, however, the method sensitivity and specificity depend on the equipment quality and the operator’s experience [4]. The use of MRI is limited by contraindications in people with kidney failure, allergy, and artificial cardiac pacemakers. PET has low sensitivity in assessment of axillary lymph node status [5].

Analysis of blood plasma is a minimally invasive method. The method may be used for diagnosis of Alzheimer’s disease [6], cervical cancer [7], lung cancer [8], and cystic fibrosis affecting liver and the lungs [9] based on the plasma molecular profile. Furthermore, the protein markers of metastasis in colorectal cancer [10] and oral cancer [11] have been found in blood plasma, along with the markers of regional metastasis.

Statistical processing of the results was performed using R scripts [17] in the Rstudio environment [18].

The search for compounds, showing significant differences in plasma levels in patients with metastases and patients with no metastases, was performed using the Mann–Whitney U-test for pairwise comparison of groups. Median (Me) and quartiles Q₁ and Q₃ were used to describe the quantitative data. The significance threshold was set at p = 0.05.

The diagnostic model based on logistic regression was built by calculating the projection of the variable using the orthogonal projection to latent structures solution [19] and selecting the compounds with the variable projection value exceeding 1. The variables were selected from the selected variables using the step-by-step approach based on the Akaike information criterion (AIC) [20] until this led to the decrease in AIC. To build the final model, the variables, the coefficients of which were not significantly different from 0 (p > 0.05), were removed from the regression in a step-by-step manner. The quality of the resulting diagnostic model was tested by leave-one-out cross-validation. Area under the ROC curve, sensitivity and specificity were used for assessment.

**Results**

During the study, we identified 183 lipid compounds in the positive ion mode and 161 compounds in the negative ion mode. Of those, four compounds showed significant differences in their levels in the positive ion mode (Table 1), and six compounds showed significant differences in the negative ion mode (Table 2). The levels of oxylipins (oxo-triglycerides in the positive ion mode and oxo-phosphotidylcholines in the negative ion mode) increased in case of metastasis. The levels of sphingomyelins, on the contrary, decreased in the presence of metastases.

Based on the constructed orthogonal projections to latent structures (Fig. 1), we selected 36 lipids in the positive ion mode and 29 lipids in the negative ion mode with the variable projection (VP) value exceeding 1.

We used seven compounds in the positive ion mode, which allowed us to build a model with the area under the ROC curve of 0.84 (Table 3; Fig. 2A), and two compounds in the negative ion mode, allowing us to build a model with the area under the ROC curve of 0.71 (Table 4; Fig. 2B). Sensitivity and specificity

**Fig. 2.** ROC curve plotted during cross-validation of the diagnostic model in the positive ion mode (A) and negative ion mode (B).
levels) and the nearby normal breast tissue (increased levels) of metastasis were observed in plasma. The varying changes significantly decreased levels of sphingomyelins upon the onset metastatic breast cancer [25]. However, in this study, the have been registered in mice’s plasma with advanced lysophosphotidylcholines in relation to phosphotidylcholines omega-6 polyunsaturated fatty acids with metastasis is known long acyl chains. The association of fatty acid synthases and together with lyso- and phosphotidylcholines, containing the pathogenesis of cancer metastasis: the ‘seed and soil’ hypothesis revisited. Nat Rev Cancer. 2003; 3 (6): 453–8.

METABOLIC “FOOTPRINTS” OF THE CIRCULATING CANCER MUCINS: CA125 IN THE HIGH-GRADE OVARIAN CANCER

Chagovets VV, Vasil'ev VG, Iurova MV, Khabas GN, Pavlovich SV, Starodubtseva NL, Mayboroda OA.

Mucins are large glycoproteins characterized by the abundant O-linked oligosaccharides (O-glycans) clustered on a protein backbone. Most of the circulating mucins are rapidly cleared by glycan-recognizing hepatic clearance receptors in the liver. Those mucins that remain in the bloodstream are most commonly used as markers in clinical diagnostics. One of such circulating mucins is MUC16; a peptide epitope of which is known as CA125 antigen — a marker for ovarian cancer. Here, using a targeted 1H-NMR profiling of plasma we are exploring a link between the measured CA125 values and the systemic metabolism of the patients within a group with confirmed high-grade ovarian cancer. The study allowed identifying statistically significant associations between the measured values of CA125 epitope and the plasma concentrations of glucose, glutamine, alanine, betaine and serine. The significance of the identified associations for the listed compounds is below 0.01. This, in turn, enables us to hypothesize about a possibility of including the metabolic measures into a composite score of the ovarian cancer based on the CA125 epitope of MUC16.

Keywords: metabolomics, NMR, circulating mucins, CA125, ovarian cancer

Funding: the study was supported by a grant from the Russian Science Foundation (project №20-65-46014).

Author contribution: Chagovets VV — study planning, sample preparation, discussion of NMR data processing, manuscript authoring and editing; Vasil'ev VG — sample preparation, NMR analysis; Iurova MV, Khabas GN — collection and characterization of clinical samples, discussion of the results; Pavlovich SV — study research, discussion of the results; Starodubtseva NL — study planning, clinical data processing; Mayboroda OA — study planning and management, manuscript authoring, NMR data processing.

Compliance with ethical standards: the study was approved by the Ethics Committee of the VI. Kulakov National Medical Research Center for Obstetrics, Gynecology and Perinatology (Minutes №10 of December 05, 2019), conducted in accordance with federal laws of the Russian Federation (№152, 323 etc.) and the Declaration of Helsinki of 1964 with all subsequent extensions and amendments regulating scientific research involving biomaterials obtained from human beings.

METABОЛОМНАЯ ПОДПИСЬ СВОБОДНЫХ МУЦИНОВ ПРИ ОНКОЛОГИЧЕСКИХ ЗАБОЛЕВАНИЯХ: СА125 И РАК ЯИЧНИКОВ ВЫСОКОЙ СТЕПЕНИ ЗЛОКАЧЕСТВЕННОСТИ

В. В. Чаговец, В. Г. Васильев, М. В. Юрова, Н. Н. Хабас, С. В. Павлович, Н. Л. Стародубцева, О. А. Майборода.

Муцины — это высокомолекулярные гликопротеины, характерной чертой которых является большое количество O-связанных олигосахаридов (O-гликанов), присущих к белковому остату. Основная часть циркулирующих муцинов быстро выводится с помощью рецепторов печени, расположенных на печени. Муцины, которые не выводятся из организма и остаются в кровотоке, наиболее часто используют в качестве клинических диагностических маркеров. Пептидный эпитоп одного из таких циркулирующих муцинов, называемого МУС16, известен как антител CA125, маркер рака яичников. Целью работы было профилирование метаболитов плазмы с помощью 1Н-ЯМР анализа и изучить связь между измеренными значениями CA125 и системным метаболизмом пациентов в группе с подтвержденным раком яичников высокой степени злокачественности. В результате исследования были обнаружены статистически значимые ассоциации между измеренными значениями эпитопа CA125 и концентрациями глюкозы, глутамина, аланина, бетаина и серина в плазме. Значимость выявленных ассоциаций для перечисленных соединений меньше 0.01. Это позволяет выдвинуть гипотезу о возможности включения метаболических показателей в диагностику рака яичников.

Ключевые слова: метаболомика, ЯМР, циркулирующие муцины, СА125, рак яичников

Mucins are large glycoproteins characterized by the abundant O-linked oligosaccharides (O-glycans) clustered on a protein backbone. They are usually localized on the surface of the epithelium, but potential sites of proteolytic cleavage are found in most mucin genes, which explains their appearance in the systemic circulation [1]. Most of the circulating mucins are rapidly cleared by glycan-recognizing hepatic clearance receptors in the liver. Those which evade the clearance and remain in the circulation are the most frequently used as the clinical diagnostic markers. One of such circulating mucins is MUC16; its peptide epitope is known as the CA125 antigen, a marker of ovarian cancer [2].

CA125 has been known for over three decades [3]. A number of large-scale clinical studies have evaluated the potential use of serum CA125 as a marker of ovarian cancer (OC). While the structural identity of the epitope remains elusive and its practical value is being challenged from time to time [4], CA125 remains the only clinically reliable diagnostic marker of ovarian cancer [5]. Here, however, we are not going to question the diagnostic value of the CA125 epitope. We address a different question, namely to which extend the CA125 values can be associated with a metabolic status of the patients. Ever since Otto Warburg discovery of the tumor cells altered metabolism a view of the cancer as a metabolic disease is steadily gaining acceptance [6]. Indeed, there is strong evidence that increased glucose consumption and increased lactate secretion in tumors promote their growth [7]. As the tumor grows, so does its need for bioenergetic resources and structural blocks. This growing need changes the systemic metabolism, which can be seen in the patient’s blood. Thus, we hypothesize that the measured values of the CA125, as a tumor marker, will have their correlates or “footprint” in the metabolic profile of plasma. To test this hypothesis, we applied targeted 1H-NMR profiling within a homogeneous selection of the patients with confirmed high-grade ovarian cancer. To find these correlates or associations, we applied an approach based on the multiple linear models adjusted for confounding variables (age and body mass index of a patient in our case).

METHODS

The study included 67 patients with histologically verified high-grade (HG) serous OC. They donated venous blood plasma samples immediately before the operation, before administration of antibacterial, analgesic and other drugs.

The inclusion criteria were: age over 18 years; histological verification of the diagnosis (HG serous OC, stage I–IV as per the FIGO (International Federation of Gynecology and Obstetrics) scale).

The non-inclusion criteria were: age below 18 years; 6 or more months of intake of hormonal drugs (combined oral contraceptives, hormone replacement therapy or menopausal therapy); US-confirmed pathology of pelvic organs and/or manifestations of the already diagnosed reproductive diseases; proliferative processes; active cancer at the time of the study or in history (any nosology other than the one studied); pelvic organ surgery; various histotype neoplasms in one patient; pregnancy.

The exclusion criteria were: histotype of the malignant ovarian tumor different from HG OC or concomitant thereto, as established through repeated examination of histological micropreparations; primary multiple neoplastic diseases not identified at the time the patient applied to the Center seeking assistance about ovarian oncoma (data on the presence thereof were obtained during the post-surgery observation).

The quantity of CA125 tumor marker in blood samples was established through the enzyme immunoassay analysis.

Preparation of samples for NMR analysis

All chemicals used in the buffers were purchased from Sigma-Aldrich (USA), with the exception of D_2O heavy water (Cortecnet; France) and 3-(trimethylsilyl) propionic-2,2,3,3-d4 acid sodium salt (TSP) (Cambridge Isotope Laboratories Inc., UK). We made two buffer solutions. Buffer A was a sodium phosphate buffer in H_2O/D_2O (80/20) with pH 7.4, containing 6.15 mmol/L NaN3 and 4.64 mmol/L TSP. Buffer B was a sodium phosphate buffer in D_2O (pH 7.4), containing 1.5 mol/L K_HPO_4, 2 mmol/L NaN3, and 4 mmol/L TSP. Ritter Deepwell 96-well plates were purchased from Novaveth BV (Netherlands), NMR tubes from Bruker Biospin Ltd (Germany). The plasma samples were thawed at 4 °C and mixed through 10 rotations of the tubes. After that, samples (120 μl) were mixed with 120 μl of buffer solution. For each sample, 190 μl of buffer and plasma mixture were transferred to 5 mm tubes with the help of a modified Gilson 215 tube filling station, and then kept at 6 °C in the sample changer.

NMR analysis and spectral data processing

1H NMR data were collected using a Bruker 700 MHz AVANCE NEO spectrometer equipped with a 5 mm Prodigy cryogenic probe head. A Bruker sample changer (Bruker; Germany) was used to feed and retrieve samples (according to the two NMR protocols: one for plasma samples and one for all other samples). All experiments were recorded at 310 K. A fresh sample of 99.8% methanol-d4 enabled temperature calibration. Axial shimming was automatically optimized before each measurement. Duration of 90° pulses was automatically calibrated for each individual sample using a homonuclear-gated mutation experiment on the locked and shimmed probe head. For each plasma sample a Purcell–Melboom–Gill (CPMG) experiment was recorded. A standard 1D CPMG pulse sequence with presaturation was used to for the acquisition of T2-filtered spectra. A pulse train of 128 refocusing pulses with individual spin echo delays of 0.6 ms was applied resulting in a total T2 filtering delay of 78 ms. After applying 4 dummy scans, a total of 73,728 data points covering a spectral width of 12,019 Hz were collected.

Identification and quantification of metabolites

Metabolites were identified by searching the full 1D and 2D JRES data using the proprietary Biobriefcode (Bruker Biospin Ltd; Germany).

The quantification of metabolites in blood samples was semi-automatic and relied on the Chenomx NMR Suite 9.0 software (Chenomx Inc.; Canada). The results of this semi-automatic quantification were processed manually. The concentrations were calculated based on the known TSP concentration (0.4 mmol/L).

**Data analysis**

All data were analyzed in the R software environment (http://www.r-project.org/, versions R 4.1.1, 4.1.2). The initial processing of the data tables relied on the tidyverse (version 1.3.1) and readxl (1.3.1) packages. Ggplot2 (version 3.3.5) and ggforestplot (version 0.1.0) enabled visualization of the results.

**RESULTS**

The sample included 67 patients, of which 11 patients had stage I or II UG OC and 56 patients — stage III or IV HG OC. The patients were comparable by age and body mass index (BMI; Table 1). The median age of patients was 53 (46; 59) years and 54 (49; 61) years, which is comparable with the data of population studies [8]. The median BMIs of the patients were 24 (21; 27) kg/m² and 25 (23; 28) kg/m².

Figure 1 shows a histogram of CA125 levels in the studied sample in the original (A) and logarithmic scales (B). The distribution based on raw values is strongly shifted to the right (median 200 U/ml, mean 742.2 U/ml). Thus, to remain within the basic assumptions of the linear models, we further used the log-transformed values of the CA125.

To get an overview of the plasma metabolites, we used a targeted 1H-NMR profiling and quantified 33 metabolites. Table 2 summarizes their medians and interquartile range values. To expand the set of parameters related to the metabolic status of patients, a set of physiologically meaningful ratios was added to the data set. Those ratios could be useful for getting insight into the amino acids metabolism and enzymatic interconversions (e.g., alanine/glutamine), gluconeogenesis (e.g., alanine/citrate), and ketogenesis (e.g., acetate/acetoacetate).

We used the linear regression models to study the relationships between metabolites and their correlations: the metabolites were used as the dependent variable and CA125.

**Table 2.** List of quantified metabolites in plasma of patients with HG OC. The values are given as median/interquartile range and rounded to the nearest whole number.

as a predictor. To correct for the known confounding factors, we added age and BMI as the model terms. All the values were scaled to enable a direct comparison of the magnitude of associations between all metabolites and their relationships. Figure 2 shows a summary of all the models. The data sorting criterion is the standardized coefficient values (descending). Filled dots correspond to the statistically significant models (correction for multiple hypothesis testing was factored in for the statistical significance p). The model characteristics for each significant association are given in Table 4 and Fig. 3.

DISCUSSION

The main goal of this study is to explore the associations between the measured values of CA125 and concentrations of plasma metabolites within a homogeneous group of the patients with clinically confirmed high grade ovarian cancer. The results indicate that CA125 levels are inversely associated with several plasma metabolites (see Fig. 2). Of all the associations, only the presence of methanol could raise questions. Nevertheless, methanol is a normal component of human plasma [9]. Its origin is mostly dietary (consumption of fresh fruits and fermented drinks); intestinal microflora also contributes to its generation. Under normal conditions, such low or "physiological" methanol concentrations are metabolized in the liver [10]. The negative association between methanol and CA125 appears to be contra intuitive, but changes in the patients’ dietary habits and decreased microbiota activity at the late stages of cancer may explain this observation. The significant negative relationship between CA125 and trimethylamine oxide, which is often interpreted as a microbiota-specific metabolite [11], serves as an additional argument in favor of the microbiotic origin of methanol. All other significant associations (glucose, glutamine, alanine, betaine, and serine) are in agreement with the changes in the systemic metabolism at the advanced stages of malignancy. While the phenomenon of glucose and amino acids (especially glutamine and alanine) depletion in the body fluids of the cancer patients...
has been reported many times, the detailed physiological mechanism of the effect remain unexplored. The decrease of alanine with a progression of malignancy could be explained by its increased utilization as a major gluconeogenic precursor, to meet the high glucose consumption by the tumor cells [12]. A decrease in the level of glutamine may be associated with more active glutaminolysis, which is required to provide precursors for the synthesis of nucleic acids [12,13]. There is no simple mechanistic explanation for the role of betaine in the physiology of malignant neoplasms. However, a recent meta-analysis has shown that betaine levels reduce the risk of cancer [14]. Indeed, as the main donor of the methyl group in the conversion of homocysteine to methionine, betaine plays a significant role in pathologies associated with altered systemic metabolism of homocysteine, folic acid, and B vitamins. Cancer, or more specifically ovarian cancer is just one of them.

Yet, looking into the model metrics for the each association (Table 4, Fig. 3) we cannot ignore the fact that despite being significant the models cover only between 10 and 15% of the variance in the data (adjusted R2). Such "noisy" models reveal the main weakness of our study, namely a rather limited pool of the patients. Another possible source of the noise is unaccounted confounding factors. In fact, while for all patients included in the current report the samples were collected before initiation of the treatment, there is no realistic way to control their dietary history and the history of medication use before the admission.

CONCLUSIONS

The study allowed identifying statistically significant associations between the measured (log) values of CA125 epitope and the plasma concentrations of a number of metabolites. Showing a link between the CA125 plasma values and metabolic composition of the plasma we for the first time describe a metabolic "footprint" of the circulated mucins. This, in its turn, allows suggesting inclusion of metabolic indicators into the CA125-based OC progress assessment.

Since CA125 discovery our understanding of ovarian cancer biology has changed to the point that these tumors are classified not only by histological attributes, but also (and mainly) on the basis their molecular phenotype. Thus, the gradual integration of metabolic parameters into the list of diagnostic methods used for stage I–IV OC is only logical.

SIGNIFICANCE OF ANALYSIS OF LIPID EXTRACTS IN CERVICAL CANAL SECRETION FOR DIAGNOSING OF PLACENTA-ASSOCIATED COMPLICATIONS OF PREGNANCY

Lomova NA, Chagovets VV, Tokareva AO, Dolgopolova EL, Karapetyan TE, Magomedova AP, Shmakov RG

Kulakov National Medical Research Center for Obstetrics, Gynecology and Perinatology, Moscow, Russia

Omics technologies hold great potential as the basis for development of the new diagnostic approaches in obstetrics. Cervicovaginal fluid (CVF) as part of the mother-placenta-fetus system can be used to diagnose obstetric complications. This study aimed to identify the features of lipid composition of the cervical canal secretion peculiar to Intrauterine Growth Restriction (IUGR) and preeclampsia (PE). We took CVF samples from 57 pregnant women and subjected them to an in-depth clinical-anamnestic and mass-spectrometric analysis. Lipid extracts of CVF were analyzed with a liquid chromatography system coupled with a mass analyzer. As a result, we identified 239 lipid compounds. In case of 17 lipids, mathematical analysis revealed significant differences between samples from women with normal pregnancy indicator values (normal group) and patients from the IUGR group (p < 0.05). As for the normal group and PE group patients, there were significant differences identified for 3 lipids (p < 0.05). Comparison of samples from the PE and IUGR groups yielded statistically significant differences in levels of two lipids (p < 0.05). Mainly, the lipids were oxylipins, sphingomyelins, triglycerides, and cardiolipins. The developed diagnostic model had the sensitivity of 0.81 and specificity of 0.91 (cut-off level — 0.50; AUC — 0.85). The data obtained are valuable in the context of development of the new methods of diagnosing placenta-associated complications of pregnancy and for understanding new mechanisms of pathogenesis of these complications.

ЗНАЧИМОСТЬ АНАЛИЗА ЛИПИДНЫХ ЭКСТРАКТОВ ИЗ ОТДЕЛЬНОГО ЦЕРВИКАЛЬНОГО КАНАЛА ДЛЯ ДИАГНОСТИКИ ПЛАЦЕНТА-АССОЦИИРОВАННЫХ ОСЛОЖНЕНИЙ БЕРЕМЕННОСТИ

Н. А. Ломова, В. В. Чаговец, А. О. Токарева, Е. Л. Долгополова, Т. Э. Карапетян, А. П. Магомедова, Р. Г. Шмаков

Национальный медицинский исследовательский центр акушерства, гинекологии и перинатологии имени В. И. Кулакова, Москва, Россия

Использование омиксных технологий имеет на сегодняшний день большой потенциал для разработки новых диагностических подходов в акушерстве. Цервиковагинальная жидкость (ЦВЖ) как часть системы «мать–плацента–плод» может быть использована для диагностики акушерских осложнений. Целью исследования было выявление особенностей липидного состава отделяемого цервикального канала у беременных с задержкой роста плода и пREE. Выполненный углубленный клинико-анамнестический и масс-спектрометрический анализ ЦВЖ, полученный от 57 беременных женщин. Липидные экстракти ЦВЖ анализировали на жидкостном хроматографе, соединенном с масс-анализатором. В результате исследования идентифицировано 239 соединений липидов. Математический анализ выявил значимые различия между пациентками группы нормы и с ЗРП (p < 0.05). Межгрупповые сравнения показали и для 17 соединений липидов. В группе нормы процент положительных значений (СЗРП) был ниже, чем в группе с ЗРП (p = 0.05). Полученные данные перспективны для разработки методов диагностики плацента-ассоциированных осложнений беременности. Показано, что липиды отличаются преимущественно на классах оксилпидов, сфингомиелинов, триглицеридов и кардиолипинов. При прионупусе диагностической модели достигнута чувствительность 0,81 и специфичность 0,91 (порог отсечки — 0,50; AUC — 0,85). Полученные данные перспективны для разработки новых диагностических подходов в акушерстве.

Ключевые слова: прогностическая значимость, неинвазивная диагностика, пREE, задержка роста плода, липидомика

Финансирование: исследование выполнено при государственном заказе Министерства здравоохранения Российской Федерации (Государственный регистрационный номер AAAA-A18-118053190026-8).

DOI: 10.24075/vrgmu.2021.066
It has been established that such common complications of pregnancy as Intrauterine Growth Restriction (IUGR) and preeclampsia (PE) are associated with placental dysfunction. With these pathologies, metabolic and circulatory systems fail to adapt to changes caused by pregnancy, which leads to hypertension and impaired placental blood flow. This not only causes undesirable consequences for the health of the mother and child during gestation, but can also affect their future health. In recent years, 10 to 20% of pregnancies in the economically developed countries have been complicated by some form of hypertension [1]. Preeclampsia is a pregnancy complication that occurs in the placenta and negatively affects both the mother and the fetus. PE is diagnosed in 5–7% of pregnant women worldwide [2]. This condition can develop after 20th week of pregnancy; its manifestations are hypertension, proteinuria and edema. Subsequently, it causes fetal distress and diminishes the chances of positive pregnancy outcome. IUGR prevents the fetus from realizing its growth potential in full: the weight and the body mass index (BMI) of the newborn are abnormal for the respective number of gestational weeks. About 4–8% of newborns are diagnosed with IUGR in industrialized countries, and in the developing countries this figure ranges from 6 to 30% [3, 4]. The causes of IUGR are distinguished into internal, peculiar to the fetus or placenta, and external, the mother-side factors affecting mainly the placenta and the fetus. There are also combinations of internal and external IUGR causes.

To date, there have not been developed adequate methods of prediction of these pregnancy complications, which obviously necessitates development of non-invasive and objective methods of prenatal diagnostics and monitoring.

Today, post-genomic omics technologies, including metabolomics and lipidomics, are growing rapidly and become more and more common in the routine clinical practice. With regard to the pathologies considered in this work, significant changes in the levels of metabolites were found even before preeclampsia manifested clinically, and these changes increase with the progression of the disorder [5–7]. Metabolomics can help detect the specific features of these conditions at the molecular level and aid in identification of the biological mechanisms underlying them, as well as in discovery of the new biomarkers. Metabonomics also offers a unique set of tools for identification of various endotypes of pathological conditions [7, 8] and diagnosing of different complications of pregnancy. Similar observations have been made for IUGR [9]. In the aforementioned works, researchers analyzed blood metabolome. Blood sampling is an invasive method of obtaining biological material. This study discusses the possibility of using cervical canal secretion to make PE or IUGR development prediction non-invasive.

Currently, the search for non-invasive and minimally invasive diagnostic markers in obstetrics is a promising area of scientific research. Cervical canal is one of the potential loci for minimally invasive sampling of biological material. There have been described potential biomarkers of spontaneous preterm labor that were identified through targeted proteomic analysis of cervicovaginal fluid samples from asymptomatic high-risk women. The proteins in cervicovaginal fluid of patients that experienced spontaneous preterm labor are extracellular matrix proteins that can also regulate the physiology of cell membranes [10]. In 2020, a statistically significant difference in the level of cytokines from cervicovaginal fluid samples, especially IL6 and IL17α, was found in the group of women with preterm labor and premature rupture of the membranes in the history. These indicators may be more accurate prognostic markers of preterm labor than fetal fibronectin that is the standard indicator relied on in clinical practice today [11]. During pregnancy, dysbiosis of the vaginal microbiota directly affects metabolic profiles, which can trigger premature birth. In 2020, researchers used nuclear magnetic resonance spectroscopy to analyze metabolic profile of cervicovaginal fluid and identified metabolic markers that can help predict preterm labor. The assessment of the ROC curve showed that acetone, ethylene glycol, formate, glycolate, isopropanol, methanol, and trimethylamine oxide were the best in the matter of predicting preterm labor. These metabolites can be useful markers clinically and for prognosis of preterm labor [12]. Thus, to date, it has been proven that the cervicovaginal fluid, which is part of the mother-placenta-fetus system, contains a number of biologically active components that can potentially be used for predicting and diagnosing obstetric pathology.

There is a wide range of methods applied to identify and validate biomarkers in metabolomic studies: ultraviolet and infrared spectroscopy, nuclear magnetic resonance spectroscopy, electrophoresis. However, the most common are metabolomic platforms based on liquid chromatography with mass spectrometric detection (LC-MS).

Metabolomics as part of studies of obstetric syndromes associated with placental insufficiency (PE and IUGR) can greatly facilitate understanding of the pathogenesis of these complications of pregnancy and development of new diagnostic and prognostic approaches.

The purpose of the study was to search for differences in the lipids of cervical canal secretion of patients with normal pregnancy and patients with fetal growth retardation and preeclampsia, as well as to develop mathematical models based on the differences found with the aim to create non-invasive methods for antenatal diagnosis of PE and IUGR.

METHODS

This was a case-control study conducted at the Kulakov National Medical Research Center for Obstetrics, Gynecology and Perinatology (Russia) from January to December 2020. The study involved 57 pregnant women, observed and helped to deliver within the study timeframe in the Center. The women were divided into three groups: Group I — 18 patients with preeclampsia, Group II — 19 patients with IUGR , Group III — 20 pregnant women without these complications, conditionally healthy (control group). Group I inclusion criteria: SBP ≥ 140 mmHg and/or DBP ≥ 90 mmHg after 20th week of pregnancy regardless of the history of blood pressure, in combination with pathological blood flow as shown with Doppler ultrasonography or EFW and/or AC values < 3rd percentile. Exclusion criteria: multiple pregnancy, cervical pathology, diabetes mellitus, impaired renal function, chronic arterial hypertension, oncological and infectious-inflammatory diseases during this pregnancy. This study did not include the cases of combined PE and IUGR. All patients delivered by caesarean section.

Collection and preparation of samples

On the day of admission to the Center, all pregnant women included in the study had their cervicovaginal secretion sampled before vaginal examination. To detect any infectious
and inflammatory diseases of the urogenital tract, a smear was taken to establish cleanliness and microbiological composition of the vagina. On average, the samples were taken 10–14 days before delivery.

The cervicovaginal secretion samples were collected with a disposable vaginal elevator and sterile disposable cytobrushes. After introduction of the elevator and visual identification of the external canal of the cervix, a cytobrush was inserted into the cervical canal to a depth of 0.5 cm and, after a clockwise rotation, removed in such a way as to avoid contact with the walls of the vagina and external genital organs. After collection the samples were cooled in liquid nitrogen and stored at −80 °C.

Before analysis, the samples were subjected to liquid-liquid extraction to obtain the lipid fraction. For this purpose, 500 μL of an H₂O/methanol (1:1) solution were added to the test tube with the cytobrush, then mixed thoroughly for 5 minutes and sonicated for another 5 minutes. After that, the cytobrush was removed from the test tube, 1 ml of chloroform added thereto and the tube stirred for 10 minutes. Next, it was centrifuged for 5 minutes at 13000 G at ambient temperature, 925 μL of the lower layer taken, dried in a nitrogen flow and redissolved in 200 μL of isopropanol/acetonitrile (1:1) solution for further analysis.

### Mass spectrometric analysis of lipid extracts

Lipid extracts were analyzed in a Dionex UltiMate 3000 liquid chromatography system (Thermo Scientific; Germany) connected to a Maxis Impact qTOF mass analyzer with an electrospray ionization source (Bruker Daltonics; Germany). Samples were separated by reversed-phase chromatography in a Zorbax C18 column (150 × 2.1 mm, 5 μm; Agilent, United States) with a linear gradient from 30 to 90% of eluent B in 20 minutes. Eluent A was a 60:40 acetonitrile/water solution with

some 0.1% formic acid and 10 mmol/L ammonium formate; eluent B was a 90:8:2 isopropanol/acetonitrile/water solution with some 0.1% formic acid and 10 mmol/L ammonium formate. The elution flow rate was 40 μL/min, and the volume of the injected sample was 3 μL. The mass spectra were obtained in the positive and negative ion mode in the range of m/z 100–1700 Da, with the following settings: voltage across the capillary at 4.1 kV in the positive ion mode and −3.2 kV in the negative ion mode; pressure of the sputtering gas at 0.7 bar, drying gas flow rate 6 L/min, drying gas temperature 200 °C.

The initial mass spectrometric data were processed with the help of msConvert software from the Proteowizard 3.0.9987 package [13], MzMine [14]. Lipid identification was performed with LipidMatch scripts [15] using the exact mass and characteristic tandem mass spectra (MS/MS). The list of lipids is consistent with LipidMaps [16].

**Statistical analysis**

We used scripts written in the R language version 3.3.3 [17] and RStudio 1.383 [18] to process the results statistically.

The analyzed parameters were checked against the law of normal distribution with the help of Shapiro–Wilk test. When the distribution of the examined value was normal, we used the Student’s t test for statistical analysis, and for the abnormal distribution cases we relied on the Mann-Whitney test for pairwise comparisons. To describe the quantitative data with normal distribution, we used arithmetic mean (M) and standard deviation (SD) in the M (SD) format. Features with distribution different from normal were described as a median (Me) and quartiles Q1 and Q3 in the Me format (Q1; Q3). The value of the threshold significance level p was taken at 0.05.

We developed the logistic regression models in order to assess the possibility of classifying patients into groups. Lipids showing statistically significant differences in levels between the groups were independent variables in the models. Akaike information criterion (AIC) enabled selection of the variables [19]. We continued selecting variables in stages while this action resulted in an increase in AIC. The quality of the resulting diagnostic model was tested by internal cross-validation with control for individual objects. The values of the area under the operating curve, sensitivity and specificity were used for assessment. The patient’s group membership was the dependent variable. For each model, we determined the Wald test, 95% confidence interval (CI), odds ratio (OR) and its confidence interval. The quality of the developed models was determined by constructing the ROC curve, determining the area under the ROC curve, and calculating the sensitivity and specificity.

**RESULTS**

Table 1 gives the results of analysis of the clinical parameters of the groups.

It was found that the BMI of pregnant women from the IUGR group is significantly lower than that of women in the "normal" and "preeclampsia" groups (p = 0.005 and p = 0.0045, respectively).
All women delivered in the third trimester of pregnancy. The delivery time for the PE and IUGR groups significantly differed from that for the control group (\( p < 0.001 \)), which is explained by the need for accelerated delivery based on obstetric indications. The share of preterm delivery in the PE group was 33.3% (six cases), in the IUGR group — 31.6% (six cases).

The average weight of newborns in the control group was 3493.6 g, compared to 2341 g and 2128.7 g in PE and IUGR groups, respectively (\( p < 0.001 \)).

It should be noted that, compared to the control group, the Apgar score in the PE group was significantly lower at the first minute of life (\( p = 0.04 \)) and in the IUGR group — at the fifth minute (\( p = 0.05 \)). One of the possible reasons behind the observations is that a newborn that suffered chronic hypoxia and growth retardation for a long period has the reserves of his/her compensatory mechanisms depleted and experiences early neonatal adaptation in severe form. One child was diagnosed with moderate asphyxia at birth, which required additional respiratory support.

Analysis of lipid composition of the cervical canal secretion was enabled by LC-MS. LC-MS experiments were performed in both positive and negative ion modes, since this approach allows expanding the coverage of registered and identified lipids. LC-MS in positive ion mode allowed identifying 129 lipids, LC-MS in negative ion mode — 110 lipid compounds. Comparison of the relative lipid levels between the control group and the IUGR group revealed 10 lipids with levels differing significantly as registered in positive ion mode and 7 lipids with significantly different levels as registered in negative ion mode (Fig. 1). The results of the comparison of control and PE groups were 1 lipid with significant level difference found in positive ion mode analysis and 2 such lipids discovered negative ion mode (Fig. 2). As for the PE to IUGR groups comparison, there were two lipids the levels of which differed significantly (Fig. 3). Mainly, the lipids were oxylipins (oxytriglycerides and oxycardiolipins), sphingomyelins, triglycerides, and cardiolipins.

Relying on the data obtained, we built the logistic regression models seeking to identify patients who may develop IUGR or PE, such identification based on the levels of lipids in the cervical canal secretion (Table 2). A ROC analysis enabled assessment of quality of the built models; Table 3 and Figures 4 and 5 present the results of this analysis. The models enabling allocation to the control and the IUGR groups had the best parameters; they made use of data obtained with both positive ion mode and negative ion mode. The AUC was 0.70 and 0.85, respectively. The model that enabled allocation to the PE and control groups had a rather high specificity (0.91) but low sensitivity (0.30). Thus, of the obstetric pathologies considered in this work (IUGR and PE), the non-invasive approach to lipid profiling based on the cervical canal secretion seems most promising for detection of IUGR. As for PE diagnosis, applicability of the described approach requires additional research. The IUGR/Normal and IUGR/PE models built on the positive ion mode and negative ion mode data can be considered for further improvement and validation.

DISCUSSION

The study allowed identifying 129 lipids with positive ion mode and 110 lipid compounds with negative ion mode; they are simple lipids, glycerides and complex lipids, which in turn are divided into glycerophospholipids and sphingolipids. The natural organic compounds of this large group, including fats and fat-like substances, participate in construction of cell membranes and regulation of metabolism. The group is undoubtedly interesting as a research subject in the context

of obstetric pathologies. In particular, there may be value in investigation of changes in the group associated with the said pathologies and, specifically, tracking the fluctuations at the interface of the mother-placenta-fetus system. Fatty acids and lipids play a primary role in growth and development during the embryonic period. Unbalanced intake of fatty acids during the perinatal period alters the composition of fatty acids in the membrane phospholipids of the fetus, which can cause structural and functional problems in its cells. In addition, the metabolic and neuroendocrine environment of the fetus and the newborn plays a key role in the energy balance regulation. Lack of proper balance between fatty acids and lipids during pregnancy can lead to irreversible changes in the control of neuroendocrine function and energy metabolism in the fetus, leading to metabolic programming. Thus, control of the lipid levels enables detection of abnormalities in the mother-placenta-fetus system even at the preclinical stage [20]. It has been shown (in both animal and human experiments) that the metabolic pathway of sphingolipids plays a critical role in fetal and maternal tolerance, regulating innate immunity at the mother-fetus interface. These findings may help develop new therapeutic strategies for obstetric complications [21].

During pregnancy, metabolic changes occur in all systems and processes of the woman’s body, including lipid metabolism. Cholesterol and free fatty acids are essential for cellular synthesis of embryonic membranes. The fetus synthesizes lipids and makes extensive use of maternal lipids, although free transplacental transport of maternal lipoproteins is limited by the “placental barrier” [22]. Phospholipids and triacylglycerols (TAGs) from the mother’s body do not penetrate directly to the fetus. There is a number of mechanisms enabling transportation of fatty acids to the fetus; these mechanisms imply binding fatty acids [23] and transporting them intensively across the placenta. Circulating lipids have a variety of effects on the endothelial cell function. Dyslipidemia is often associated with dysfunction of these cells [24]. Several studies have shown a concentration-dependent relationship between elevated TAG levels and the risk of PE. There are many mechanisms that may be used as explanation of the correlation between dyslipidemia and PE. For example, increased levels of lipid fractions (such as TAG) trigger their accumulation in endothelial cells and subdue production of prostacyclin, which subsequently leads to endothelial dysfunction [25]. In our study, the level of TG 18: 1_24: 0_24: 1, CL 16: 0_16: 1_22: 6_22: 6, PC O-22: 1/18: 1 had significant differences in the PE-Normal groups comparison (p = 0.008, p = 0.02, p = 0.04, respectively). The specificity achieved for the PE/Normal diagnostic model is 0.91 (cut-off threshold — 0.10; AUC — 0.67).

In case of IUGR, placenta does not function properly and has its structure compromised, and the manifestations of the problem are detectable with the fetus but not with the mother’s body. Several researchers [26, 27] have found that during pregnancy complicated by IUGR, there is a decrease in the level of lipids in the umbilical cord blood and the mother’s blood, and the number of their receptors goes down, too. Low levels of lipids and their receptors in the feto-placental complex will probably have very serious consequences for the normal growth and development of the fetus, since they

Fig. 4. Operational curve plotted for the IUGR/Normal model based on the positive ion mode (A) and negative ion mode (B) data

Fig. 5. Operational curve plotted for the PE/Normal model (A), IUGR/PE model based on the positive ion mode data (B)
will only insufficiently enable transport of cholesterol, normal functioning of the placenta and harmonious growth of the fetus. As we have registered in our study, the levels of 17 lipids (Table 2) were significantly different in the IUGR and the Normal groups (p < 0.05). The specificity achieved for the PE/Normal diagnostic model is 0.91, sensitivity is 0.81 (cut-off threshold −0.50; AUC — 0.85).

The significant difference in the results of examination of cervicovaginal secretion samples taken in the IUGR and PE groups (p = 0.04) is of particular interest. This difference clearly demonstrates that these pregnancy complications, initially considered to stem from the common placental dysfunction, are not the same on the pathogenic level.

CONCLUSIONS

Our study clearly demonstrates the possibility of using cervicovaginal fluid in complex diagnostic monitoring of pregnant women with placenta-associated obstetric complications. We performed an in-depth clinical-anamnestic and mass-spectrometric analysis of samples taken from 57 pregnant women. Analysis of the cervical canal secretion of pregnant women with IUGR and PE revealed 129 lipid compounds when using LC-MS in positive ion mode and 110 lipid compounds with LC-MS in negative ion mode. The level of a number of lipids differed significantly between the PE and Normal groups and the IUGR and Normal groups. This observation may indicate the existing differences in the chain of biological processes of the pathogenesis of these pregnancy complications that are commonly believed to stem from placental dysfunction. Further research in this direction may help identify new approaches to the development of targeted therapy for the “major obstetric syndromes.” The lipids were mainly oxylipins (oxytriglycerides and oxycardiolipins), sphingomyelins, triglycerides, and cardiolipins, which means this method may be used as part of a complex of predictive measures. Based on the differences identified, we built logistic regression models that can contribute to the development of methods of non-invasive diagnostics of these diseases. The result of our effort is the clear demonstration of the possibility to determine the level of lipids in the cervicovaginal fluid non-invasively in the context of complex diagnostic monitoring of pregnant women with placenta-associated obstetric complications.

The aim of the current study was to evaluate the diagnosis and treatment of DEC during pregnancy. A total of 82 female patients were included in the study: 63 had endometrial cysts (EC), 16 had DEC, and 3 had rare forms of endometriosis. The ultrasound imaging parameters, being the most valuable for differential diagnosis of EC, DEC, and serous tumors, were as follows: the altered mass wall thickness, the existence and shape of papillary masses, avascular echogenic inclusions with blurry contour, blood circulation and arrangement of blood vessels, ascites. The frequency analysis revealed the differences between groups based on the ultrasound imaging data (in 60–100% of observations). Histological examination revealed the differences between groups in 100% of observations. Our findings have made it impossible to prolong pregnancy in patients with DEC without performing surgery. The results of treatment provided to patients with DEC during pregnancy were worse compared to those in patients with no prominent decidualization in ovarian EC. Today, the diagnosis of DEC and the treatment of patients during pregnancy remain unsophisticated. Further clinical observation and the search for more reliable methods of the diagnosis and rational treatment of pregnant women with DEC are required.

Keywords: ultrasound examination, morphological analysis, ovarian tumors, pregnant women

В настоящее время при наличии децидуализированных эндометриоидных кист яичников (ДЭК) хирургическое лечение для исключения злокачественных опухолей женщин выполнено практически в 90% случаев. Неоправданное хирургическое вмешательство при этом увеличивает риск для здоровья матери и плода. Целью исследования было провести дифференциальную диагностику ДЭК у беременных для определения рационального лечения. В исследование включены 82 пациентки: 63 из них были с эндометриоидными кистами (ЭК), 16 — с ДЭК, 3 — с редкими формами эндометриоза и 10 — с серозными папиллярными пограничными опухолями яичников. Для ультразвуковой (УЗ) диагностики использовали предложенную авторами модель. Полученные УЗ-данные сопоставляли с концентрацией белка-онкомаркера (CA-125), рассчитывали индекс RMI (risk of malignancy index), выполняли морфологическое исследование образований. Особо ценными УЗ-параметрами при дифференциальной диагностике ЭК, ДЭК и пограничных серозных опухолей были: измененная толщина стенки образования, наличие и форма папиллярных образований, васкулярные экогенные включения без четких контуров, кровоток и расположение сосудов, асцит. Результаты частотного анализа показали различия между группами по данным УЗИ (в 60–100% наблюдений). Гистологическое исследование выявило различия между группами в 100% наблюдений. Полученные результаты не позволили нам пролонгировать беременность при ДЭК без выполнения хирургического лечения. Результаты лечения пациенток с ДЭК во время беременности были хуже таковых без выраженной децидуальной трансформации ЭК яичников. В настоящее время диагностика ДЭК и лечение больных во время беременности остаются несовершенными. Необходимы дальнейшие клинические наблюдения и поиск более надежных способов диагностики и рационального лечения беременных с ДЭК.

Ключевые слова: ультразвуковое исследование, морфологическое исследование, опухоли яичников, беременность

DOI: 10.24075/vrgmu.2021.059
Ovarian endometriosis is a chronic tumor-like lesion observed in 1–2% of pregnant women [1]. In 12% of women, the foci of endometriosis may undergo decidualization, and emerge as early as at 9 weeks of gestation [2].

Decidualization is a benign transient lesion, observed during gestation. It is usually found during the caesarian section or surgical treatment of masses with high risk of malignization. The decidual regression occurs in 4–6 weeks after delivery [3]. According to some reports, lower levels of decidualization in the postpartum period [4] are associated with high progesterone levels, absence of menstrual periods, and increased apoptosis being the key factor of endometriosis regression.

Decidualized endometrial cysts (DEC) are almost always asymptomatic during pregnancy. When performing ultrasound examination of DEC, the majority of authors distinguish the combination of the cystic cavity with a large amount of suspended debris, typical for EC, and papillary projections with increased vascularity. These echographic characteristics are similar to those of malignant ovarian tumors. Surgical interventions aimed to exclude the malignant ovarian tumors in patients with DEC are performed in almost 90% of observations [5, 6]. Unnecessary surgical interventions increase the risk to maternal and fetal health [7–11].

Thus, despite the fact that in pregnant women decidualization is characterized by benign course, it becomes the cause of numerous complications, and the presence of macroscopic features similar to those of malignant tumors may result in unnecessary therapeutic interventions.

The study was aimed to perform a differential diagnosis of DEC in pregnant women in order to define the rational treatment.

METHODS

A total of 82 female patients with endometriosis verified by histology were enrolled in the study, which was carried out in 2000–2021. The age of the patients examined varied between 19–41 years (the median age was 31 years). Inclusion criteria: consent to participate in the study; pregnancy; ultrasound examination performed with the Voluson E8 ultrasound machine (General Electric; USA) with the use of the 450 MHz transvaginal probe at a frequency of 12.8 MHz. Exclusion criteria: pregnant woman’s refusal to participate in the study; threatened abortion; intrauterine infection; prenatal injury identified before the study.

In group 1 (control group), ultrasound examination performed during pregnancy revealed no signs of decidualization in 63 patients out of 82. These patients had a caesarean delivery due to combined indications: endometriosis and breech presentation in 9 patients, acute fetal hypoxia in 10 patients, unprepared birth canal and hypotonic labor in 11 patients, postpartum pregnancy and threats to the fetus in 10 patients, severe preeclampsia in 4 patients, symphysitis in 5 patients, uterine scar in 6 patients, placenta praevia in 4 patients, primary infertility and in vitro fertilization (IVF) in 4 patients. After the delivery and histological examination of ovarian masses (OM), decidualization in the ovaries was the finding revealed in 43 of these patients.

Among 63 deliveries, 5 (7.9%) were preterm. Of those in 1 case severe preeclampsia developed at 29 weeks, and the treatment was ineffective; in 2 cases at 32 weeks there were placenta previa with hemorrhage (1 patient) and premature rupture of membranes (PROM) (1 patient); in 2 cases at 35–36 weeks there were placenta previa with hemorrhage (1 patient) and acute fetal hypoxia (1 patient).

In 16 patients of group 2, decidualization in the ovary was found at 16–28 weeks (the median value was 17) of pregnancy, having the signs resembling malignization, that is why laparoscopic adnexectomy (one case) with oophorectomy (four cases) was performed, as well as laparotomy with adnexectomy (four cases) and oophorectomy (seven cases). When performing laparotomy, the abdominal cavity revision was performed, together with tissue specimen collection and rapid morphological examination.

Three patients had the severe decidual reaction and rare complications of endometriosis. In one patient, who had the caesarian delivery, endometrial implants were found during the surgical procedure. The focus of deciduosis were located on the uterine surface, omentum, peritoneum, and were represented by numerous yellowish elastic nodules of various sizes, the largest of which were almost 4 cm in diameter. In two women, decidualization was diagnosed in the colon wall, resected on days 2 and 5 after delivery due to the symptoms of acute abdomen.

When performing a differential diagnosis of DEC, we used the earlier results (control group 2) [12] obtained for 10 patients with ovarian serous papillary borderline tumors.

Ultrasound examination was performed with the Voluson E8 ultrasound machine (General Electric; USA) with the use of
transabdominal and transvaginal color Doppler imaging and pulsed wave Doppler velocimetry. Ultrasound characteristics of the tumors were assessed using the earlier proposed models [13]. The 2D and 3D comprehensive ultrasound examination was combined with color Doppler (CD) and power Doppler (PD), as well as with 3D angiography. Diagnostic ultrasound was performed with the use of our proposed model, allowing one to distinguish between benign, borderline and malignant tumors [13]. When assessing the model accuracy, sensitivity (Se) and specificity (Sp) were used along with the count of correct assignments.

The concentration of CA-125 was assessed by enzyme immunoassay using the test system (Siemens; Germany).

RMI was defined in accordance with the guidelines [14, 15] using the following formula:

$$\text{RMI} = M \times U \times \text{CA-125},$$

where \( M \) — menopausal status in points, \( U \) — ultrasound results in points, \( C \) — serum CA-125 level (IU/mL).

RMI ≥ 200 was regarded as a sign of the high likelihood of epithelial ovarian cancer.

Tissue specimens stained with hematoxylin and eosin were assessed by different pathologists. Morphological diagnosis was established in accordance with the WHO classification of tumours of the female reproductive organs (2014). Paraffin-embedded tissue blocks were selected for immunohistochemistry; 15 blocks from patients with EC, and 10 blocks from patients with DEC. Morphological assessment was performed by standard methods. The diagnosis of deciduosis was confirmed by immunohistochemistry with the use of Vimentin (3B4, Ventana) and CD10 (56C6, Ventana) antibodies, being the markers of mesenchymal tissue and endometrial stroma, respectively. Intestinal tissue specimens were assessed as reference material when assessing the expression of Vimentin, and the tonsillar tissue specimens were used when studying the CD10 immunoreactivity; when performing immunohistochemistry, the samples of the studied tissue not treated with primary antibodies were used as a negative control for both markers. Positive staining for both markers was subjectively classified as weak, moderate, or strong.

In addition, medical records together with the pregnancy and childbirth outcomes were studied in these 82 patients after treatment.

Statistical data processing was carried out using the SPSS 15.0 software package (IBM; USA). The data were subjected to frequency analysis by constructing the crosstabs. The differences were considered significant when \( p < 0.05 \).

RESULTS

Ultrasonography showed that in the majority of observations in group 1, EC (\( n = 63 \)) were small, located inside the ovaries, with smooth outer and inner contours, the cyst content was of moderate or high echogenicity, blood vessels were visible in the walls. A total of 60 EC (95%) were unilateral: right-sided in 18 patients (30%), left-sided in 42 patients (70%). Bilateral cysts were found in three observations. In about 5% of 63 observations, EC had intracystic masses of moderate or high echogenicity, vessel arrangement, and the resistive index (RI) were of the greatest informational value. The maximum EC score obtained using the decision procedure did not exceed 2 points.

When performing the differential diagnosis of EC with the use of our proposed method [13], the patient’s age, blood vessel arrangement, and the resistive index (RI) were the greatest informational value. The maximum EC score obtained using the decision procedure did not exceed 2 points.

Performance of the model for EC identification (Fig. 1) was 84%, however, the area under the ROC curve was very large, indicating the high quality of the model.

Preoperative evaluation of the patients in group 1 revealed no peculiarities in the ultrasound imaging parameters, CA-125, RMI in puerperant women with no deciduosis and those who had deciduosis, which was identified as a finding when performing the histological examination.

Blood levels of CA-125 in patients varied between 2.7 and 131.2 U/mL, the average level was 61.1 ± 8.5 U/mL.

</table>

RMI varied between 7.3 and 131.2, the average value was 65.4 ± 9 (the median value was 59). In the group of patients with EC, about 98% had RMI of less than 200. Moreover, in 19 patients (31%), RMI was below 25, in 28 patients (44%), it was 25–100, and only in 16 patients (25%), the observed RMI values exceeded 100, but never reached 200.

The planned caesarean section results in this group were as follows: all children were born in satisfactory condition. The Apgar score was 6–8 (the median value was 7.8) in premature babies and 9–9 (the median value was 8.9) in full-term babies. The birth weight was 1880–2840 g (the median value was 2640 g) in premature babies and 2660–4480 g (the median value was 3530 g) in full-term babies. Three premature babies needed the 2nd stage developmental care. In other babies, the early neonatal period went smoothly, the patients and their babies were discharged from the maternity hospital on day 5–7 after surgery. The morbidity rate was 3.2%.

Morphological examination of non-decidualized EC showed that the walls of ovarian cysts consisted of ovarian tissue with fibrotic changes, inner layer of cytogenic stroma with hemorrhages and hemosiderin deposition, and the lining epithelium was of endometrioid type. In DEC identified as findings, the fragments of the cystic ovarian endometrioma wall were defined with no lining epithelium, large areas of decidualization involving hypertrophy of endometrial stromal cells into polygonal cells with clear margins, abundant eosinophilic cytoplasm, round to oval nuclei with fine granular chromatin; no mitosis was detected.

When performing ultrasound examination in group 2 (n = 16), DEC were identified as the masses secured to the walls of the pelvis, located low relative to the gravid uterus. In 10 pregnant women (62.5%), DEC were unilateral, right-sided DEC were found in 7 patients (70%), and left-sided DEC were identified in three patients (30%). Bilateral ovarian lesions were reported in six observations (37.5%).

DEC were characterized by cystic and solid ovarian mass structure in all observations, multiloculated structure in four patients (25%), or incomplete septa in four observations (25%), irregular wall thickening with highly vascularized mural structures having multiple coloured loci of blood flow and low resistive index values in all masses.
When reviewing the data obtained, it should be noted that with strong positive cytoplasmic immunoreactivity for Vimentin stromal cells of the foci with decidualization (Fig. 4B) together with moderate positive cytoplasmic expression of CD10 in the deposition within the wall. Immunohistochemistry revealed endometrioid type, with hemorrhagic foci and hemosiderin latter had a typical structure, were lined with epithelium of all observations. Morphological evaluation showed that the DEC group differed from the groups with EC and borderline markers. The results of histological examination made it possible to distinguish the combination of the cystic cavity with a large amount of suspended debris, typical for EC, and papillary projections with increased vascularity among the echographic signs of DEC [7–11]. When there is a DEC, the sonographic features are similar to those observed in patients with malignant ovarian tumors based on the echographic characteristics. Our records (Table) show that today the use of generally accepted non-invasive preoperative diagnostic tests makes it possible to distinguish between EC, DEC, and borderline tumors with a high probability. The comparison of DEC with borderline tumors (with the control group 2) revealed significant fluctuations in the studied indicators, however, based on the ultrasound imaging data, these were distinguishable in the majority of observations. In modern medicine, the good test (marker) is the one that is not found in 70% of the comparison group when comparing two groups.

When performing the differential diagnosis of the studied groups (Table), the following ultrasound imaging parameters were the most valuable: the altered mass wall thickness, the existence and shape of papillary masses, avascular echogenic inclusions with blury contour, blood circulation and arrangement of blood vessels, ascites. The frequency analysis showed that the DEC group differed from the groups with EC and borderline tumors in 60–100% of observations based on the sonographic markers. The results of histological examination made it possible to perform a differential diagnosis of EC, DEC, and borderline tumors in 100% of observations.

Given that the assessment of the studied sonographic markers is still subjective, and the findings have made it impossible to eliminate the high risk of the mass malignization in patients with DEC, these patients have undergone surgery in early pregnancy. Echographic image of DEC suspicious for malignization has made it impossible to prolong pregnancy for ethical reasons, even with the possibility of the increased rate of perinatal complications. The need for surgical treatment...
aimed to exclude the malignant ovarian tumors in patients with decidualized EC (DEC) is in line with literature data [5, 6], this treatment method is applied in almost 90% of observations.

Adverse pregnancy outcomes in patients with endometriosis relate primarily to miscarriage, high risk of preterm labor and low birth weight babies [18–20].

Pregnancy and labor in patients with endometriosis are associated with high risk of complications, such as hematopentoneum, bowel perforation, appendicitis, and EC rupture [19, 20].

Other complications of pregnancy are observed in patients with decidualization. Thus, in one of the trials, histological examination revealed decidual changes in all layers of appendix on day 5 after caesarean section and non-neoplastic appendicitis [21]. During our study, multiple yellowish elastic nodules of various size (up to 4 cm), located on the uterine surface, omentum, and peritoneum, were found during the surgical procedure in one patient, who had caesarean section for obstetric reasons (Fig. 5).

The fragments of omentum were resected for further histological examination, which revealed prominent decidual changes. In the other two patients, we had to perform re-surgery during the postoperative period (on days 2–5 after the caesarian section performed for obstetric reasons) due to acute abdomen. The macroscopically altered fragments of the colon with decidualization in the wall and multiple endometrioid heterotopias with decidual changes in all layers of the colon wall were resected.

There is evidence of similar immunohistochemistry features in the extratubal mesenchymal cells that have undergone the decidual reaction, and decidualized endometrial stromal cells with positive expression of mesenchymal markers (Vimentin, Desmin), and progesterone receptors [22]. Reduced concentration of progesterone, resulting from pregnancy termination triggers the involution of foci with decidualization, which in some cases is followed by severe circulatory disorder and decidual tissue destruction, probably entailing the pain symptoms and hemorrhage [23, 24]. Intra-abdominal hemorrhage was revealed on day 7 after the caesarian section in the patient, having the focus with decidualization, located in the area of the uterine posterior wall on the i.f. [25, 26].

Thus, decidualization in pregnant women is characterized by a benign course, however, it becomes the cause of numerous complications. The presence of macroscopic features similar to those of malignant tumors may result in unnecessary therapeutic interventions.

CONCLUSIONS

Currently, the diagnosis of DEC and the treatment of patients during pregnancy give rise to many questions. Further clinical observation and the search for more reliable methods of the DEC diagnosis and rational treatment in pregnant women are required.

RESISTIVE INDEX OF INTERNAL CAROTID ARTERY AND BRAIN NETWORKS IN PATIENTS WITH CHRONIC CEREBRAL ISCHEMIA

Fokin VF, Ponomareva NV, Medvedev RB, Konovalov RN, Krotenkova MV, Lagoda OV, Tanashyan MM

Research Center of Neurology, Moscow, Russia

Quantitative assessment of cerebral hemodynamics is important for patients with chronic cerebral ischemia (CCI), as it helps to reveal the pathogenesis of the disease and set the course for effective prevention and treatment. The study was aimed to assess the correlation of the left carotid artery (ICA) resistive index (RI) with cognitive functions and brain network organization based on fMRI data in patients with CCI (51 males and 105 females). The listed above indicators were studied in patients with the left ICA RI values below and above the average (0.54 ± 0.013). The lower, normal physiological ICA resistance levels corresponded to the more successful realization of verbal cognitive functions. In the first group, RI was within normal range (RI = 0.42 ± 0.007), and in the second group RI exceeded normal levels (RI = 0.61 ± 0.01). Variation of the right ICA RI did not correlate with the characteristics of verbal cognitive functions. fMRI data analysis was used to assess the differences in connectivity between various brain regions in the groups with low and high RI. The normal physiological and elevated RI values of the left ICA correlated with differences in the organization of brain networks: normal physiological RI values corresponded to a better organization of hemispheric connections in the basal ganglia and brainstem, and high RI values corresponded to a better organization of connections between the frontal regions and the cerebellum as well as occipital areas of the cerebral cortex. The left ICA RI can be considered as a biomarker of cognitive decline and brain networks reorganization in patients with CCI.

Keywords: chronic cerebral ischemia, internal carotid artery, resistive index, cognitive functions, neural networks

Chronic cerebral ischemia (CCI) is among prevalent socially significant vascular diseases [1]. Maintaining the normal levels of cerebral circulation is a major challenge for patients with CCI. In this regard, the internal carotid artery (ICA) blood flow plays a vital part in maintaining the normal function of the brain. There are numerous papers, which demonstrate that impaired cerebral circulation through ICA results in hypoxia, structural and functional changes in the basin of ICA, and cognitive impairment, especially in case of impaired left ICA blood flow, since the left hemisphere is involved in organization and regulation of many cognitive functions in right-handed individuals [2]. There is a number of cerebral blood flow indicators, commonly used to characterize circulation: linear blood flow velocity and volumetric blood flow rate, resistive index (RI), etc. RI has been used in our study, since this is a composite indicator being the difference between the systolic
and diastolic blood velocities divided by the systolic velocity. Along with the intima-media complex thickness, this indicator is used to describe cerebral arteriosclerosis. RI shows an upward trend with the progress of CCI and small vessel diseases [3].

Another aspect just as important in this problem pertains to the question of which neurophysiological mechanisms the increased ICA RI values are related to. Currently, the concept of “brain networks” is widely used, significantly owing its development to the success of functional MRI (fMRI). The concept of connectivity, i.e. the synchronized changes of blood oxygen level-dependent (BOLD) signal, which, according to many researchers, indicate the involvement of these regions in the joint functional system, is the key concept in brain network research. The BOLD signal changes reflect the transition of hemoglobin, contained in red blood cells, from oxidized to reduced form in various brain structures. Temporal correlations of low-frequency BOLD signal fluctuations in various brain regions reveal the organized functional brain networks. Connectivity, derived from resting state fMRI data, provides the means to describe and investigate intercentral relationships, it is considered a potential biomarker of neurological and mental disorders [4, 5].

Depicting of neural networks made it possible to better understand the dynamics of nerve centers in cerebrovascular disorders leading to neuron dysfunction and their death.

With the development of chronic disorders of cerebral circulation, the cortical nerve centers and other structures of the brain are disproportionately affected, which leads to the emergence of a new neural organization. Thus, according to the authors of [6], the volume of the hippocampus, thalamus, putamen, angular gyrus and other structures depends on the level of oxygen saturation in the blood, but the structures listed in the table functional system is sensitive to the density of capillaries density of neurons varies in different areas of the brain, and the skin gills are much more uniform [7]. Therefore, it can be assumed that increased arterial stiffness due to atherosclerosis, reflected in an increase in RI and accompanied by hemodynamic disorders, will affect the reorganization of the brain network due to hypoxia occurring in the most vulnerable areas of the brain [8]. This determines the relevance of studying RI in order to solve a whole range of problems related to the CCI. Two of these problems are the most significant: the correlation of the above indicator with cognitive functions and the relationship between RI and brain networks.

The study was aimed to assess the correlation of ICA RI with cognitive decline and the indicators of the resting-state networks in patients with CCI.

METHODS

The study was carried out in 2019–2021 at the Research Center of Neurology. A total of 156 patients with CCI (51 males and 105 females) aged 51–85 (the average age was 67.0 ± 0.69 years, SD 8.74) were enrolled. Cognitive impairment is observed in patients with CCI, the patients differ mainly in quantitative characteristics of memory impairment, performance, irritability, brainstem symptoms, etc. The main etiological causes of CCI in the patients examined were as follows: atherosclerosis, arterial hypertension (including the hypertension disease), venous insufficiency, etc. Arterial hypertension (stage 1 and stage 2 hypertension) was found in all patients. Patients with atherosclerotic plaque buildup in the ICA and ICA stenosis up to 60% were selected for the study.

Inclusion criteria: compliance with stage I or II dyscirculatory encephalopathy; patients, who did not need constant care in their daily life. The patients with stage I or II dyscirculatory encephalopathy differed mainly in quantitative characteristics of cognitive functions and had no history of acute cerebrovascular accidents. Exclusion criteria: dementia rated 1 or higher on the Clinical Dementia Rating Scale [9], the history of acute cerebrovascular accidents (all patients underwent MRI of the brain, in particular to exclude “silent” brain matter lesions, the diffusion-weighted imaging mode was used with a diffusion-weighting factor b = 1000), traumatic brain injuries, severe cardiac or metabolic (type 2 diabetes mellitus) decomposition, stages 3–5 of chronic kidney disease, uncompensated thyroid disease (hypothyroidism). All the subjects were right-handed. Contemporary ideas about the approaches to studying CCI, as well as about dyscirculatory encephalopathy, are described in detail in a number of papers [10–12].

The psychometric assessment included Luria’s verbal memory test [13], adapted for patients with this type of vascular disorder. We estimated the total number of words memorized by the patients after five repetitions of 10 words. After the test, we performed a sequential countdown (subtraction from 100 to 7) and evaluated the number of words memorized. The fluency test took into account the number of memorized words beginning with the letters S-, A-, P-, A., patients. In the traditional version of the Rey–Osterrieth complex figure test, the subjects were asked to draw a picture on a blank sheet of paper. Patients also performed a letter recognition test based on the Kirschnern k-back test (the subject found two identical letters next to each other in the given without spaces), describing the ability to recognize letters non-verbally. pattern and concentration of attention [14].

Patients of both genders (20 males and 35 females) were subjected to T2*-weighted resting-state fMRI in order to detect the BOLD signal using the MAGNETOM Verio 3T MRI system (Siemens; Germany). The subjects were offered the following instruction: to relax as much as possible, to lie still with their eyes closed in order to avoid stimulation of the visual sensory system, and not to think of anything special. Preprocessing of MRI data was performed using SPM12 software (Functional Imaging Laboratory at University College London; UK) in the MATLAB environment (MathWorks; USA). Connectivity was assessed using the CONN-18b application (McGovern Institute for Brain Research, Massachusetts Institute of Technology; USA) of the SPM-12 software toolbox [15].

Note: n — number of examined patients; p — significance level, females; blank cells correspond to no significant correlation.
Duplex ultrasonography was performed in all patients. Linear and volumetric systolic and diastolic blood flow velocities were assessed in the right and left ICA. Color-flow duplex ultrasonography was carried out using the Toshiba Viario system (Toshiba; Japan). The nature and the values of linear and volumetric systolic blood flow velocities and RI of the arteries were studied using a generally accepted method with the linear probe 5.0-12.0 MHz. RI was calculated as the difference between the systolic and diastolic blood flow velocities divided by the systolic blood flow velocity.

FMRI was used to assess brain network connectivity in 55 patients, being in a quiet waking state. Connectivity was compared between two groups of patients, which differed in RI. Connectivity between two brain structures is equal to the regression coefficient of BOLD signals in these structures. The differences in connectivity between groups with low and high RI were assessed based on the standardized regression coefficients adjusted for multiple comparisons (false discovery rate, FDR) [15]. The average RI values for both groups are provided in the Results section. This sample of patients (n = 55) was similar (p > 0.05) to the sample used for RI assessment (n = 156) based on RI values and psychological test scores.

Connectivity was assessed using the Statistica-12 software package (StatSoft; USA) for analysis of variance and other methods of studying variation, together with SPM-12 and CONN-18b applications in the MATLAB environment. Connectivity and the differences in connectivity between groups were assessed using multiple testing corrections taking into account FDR. The differences were considered significant when p < 0.05.

RESULTS

The right and left ICA RI values were not significantly different, these were 0.564 ± 0.011 and 0.548 ± 0.013 respectively. There were no significant differences in RI between the right and the left ICA in males and females (significance level for males p = 0.96, significance level for females p = 0.21). The right and left ICA RI values correlate with each other, and the correlation coefficient is significant with a very high significance level (r = 0.69; n = 154; p < 0.00001), that is why bilateral differences depend little on RI values, which may vary in different disease stages.

Studying the correlation of the right and the left ICA RI values with cognitive functions has shown that the main correlation is observed with the characteristics of blood flow through the left ICA (Table 1).

All the correlation coefficients were negative, which meant that the smaller the RI, the better the cognitive indicators (see Table 1). In men, there was a significant correlation between the left ICA RI and the delayed recall score (p = 0.009).

Characteristics of the right ICA RI correlated with recognition of nonverbal letter patterns, and the left ICA RI correlated with the characteristics of verbal fluency, immediate recall, and delayed recall.

Fig. 1 demonstrates the correlation of the left ICA RI with some cognitive indicators (verbal fluency and delayed recall) in the mixed-gender group. In both cases, lower RI values, which were closer to the normal physiological values, corresponded to better preserved cognitive functions.

The average verbal fluency in all examined patients was 12.9 ± 0.31 words (see Fig. 1A). The average value of this indicator in patients with low verbal fluency (less than 13 words (–1)) was 10.0 ± 0.23 words (SD = 2.03, n = 76). In the group with verbal fluency exceeding 13 words (1), the average value of the indicator was 16.2 ± 0.34 words (SD = 2.69, n = 62).

In a similar fashion, the low and high delayed recall scores were less or more than five words, i.e. the half of the maximum recall score of 10 (see Fig. 1B). In the group with low delayed recall score (–1), the average value was 3.0 ± 0.19 words (SD = 1.18, n = 40). In the group with high delayed recall score (1), the average value was 7.3 ± 0.44 words (SD = 1.19, n = 77).

Thus, the relatively preserved cognitive functions were associated with lower left ICA RI values with a rather high significance level (p < 0.001) (Fig. 1B).

RI values for delayed recall are of prime interest, since in this case it may be said that brain plasticity impairment, associated with poor vocabulary recall scores, starts when RI exceeds 0.55. In the case it may be said that brain plasticity impairment, associated with low delayed recall values (–1) was 0.48 ± 0.03 words. In the group with low delayed recall values, the average value was 0.54 ± 0.013. It is interesting, because this is consistent with the average RI value of 0.54 ± 0.013.

The varying degrees of success in realization of cognitive functions depending on the left ICA RI raise the issue of the brain network state under these conditions. All subjects were divided into two groups with RI values above or below the average (the average values in these groups were 0.42 ± 0.007 and 0.61 ± 0.010, respectively). Fig. 2A demonstrates that higher indicators of interhemispheric connections in the basal ganglia, insular cortex, and cerebellum constitute the

![Fig. 1. Left ICA RI in patients with low and high cognitive test scores. A. Left ICA RI in patients with low (–1) and high (1) verbal fluency. B. main difference between brain networks in patients with normal physiological RI compared to blood flow in patients with more stiff vascular walls (high RI). The relatively higher connectivity of neuronal networks of the cerebellum and a part of sphenoidal cortex with the frontal regions, comprising frontal pole and motor regions, were observed in patients with higher RI. The reported effect did not correlate with age, since the group with lower RI was older (68.8 ± 1.5 years), and the group with higher RI was younger (62.9 ± 2.1 years).

The differences were statistically significant at \( p = 0.025 \). However, in the older group, higher indicators of cognitive functions were observed, especially indicators of delayed recall. This could be due to the peculiarities of the sample of a random variable, as well as to the different degree of malignancy of the disease in patients of different age groups, as in other diseases (Alzheimer’s disease, etc.).

Statistical parameters of the discussed connections are presented in Table 2.

The data obtained demonstrate that strong interhemispheric connections in the basal ganglia and cerebral cortex are probably the factor associated with preserved cognitive functioning.

**DISCUSSION**

The average RI values in patients with CCI, registered during our study, were close to the index values, registered in older people of appropriate age. Some authors point out that RI of 0.7 is the upper boundary of the normal range in people of elderly and senile age [16]. Our records show that in patients with CCI this boundary for the left ICA passes through 0.55. Regardless of the system of the circle of Willis, blood flow through the left and right ICA has more to do with blood supply of ipsilateral hemisphere than with blood supply of contralateral hemisphere. Therefore, the decreased (primarily due to atherosclerosis) left or right carotid artery blood flow affects various cognitive functions or, according to some authors, verbal and nonverbal intelligence [2]. According to our information, cognitive processes, associated with verbal functions, correlate with the left ICA RI, and those, associated with nonverbal functions, correlate with the right ICA RI.

Mild cognitive impairment is often observed in patients with unilateral stenosis and high ICA RI. However, the functional and structural integrity of brain networks has been reported. Alternatively, the developing cognitive decline is almost always

accompanied by brain network alterations. Thus, cognitive deficit is an important indicator of the neuronal network rearrangement [4]. The fact, that blood flow through the left and right carotid arteries is strongly associated with blood supply of ipsilateral hemisphere, is important. This means that the decreased blood flow through the left ICA is followed by impaired cognitive, mainly verbal, functions, and the decreased blood flow through the right ICA is often asymptomatic and is seldom related to verbal functions. It is our assessment that structural impairments in neuronal networks, and cognitive decline in the context of abnormal hemodynamics and increased RI result from the functional decline in various brain structures due to unequal sensitivity of those to oxygen deficiency. This occurs for two reasons: because of different sensitivity of the cortex and subcortical structures to oxygen deficiency, and because of focal and diffuse lesion in brain structures, common to CCI. No MRI-visible foci were found in the studied sample.

However, brain self-regulation, being the principle of brain functioning, is preserved, but the functional system is formed by different neurons. Reorganization of the resting-state brain networks is observed in patients with stenosis in either one or both ICA. This is probably due to subtle white matter integrity disruptions. In general, hemodynamic disorders in one or both ICA. This is probably due to subtle white matter brain networks is observed in patients with stenosis in either one or both ICA. This is probably due to subtle white matter integrity disruptions. In general, hemodynamic disorders in one hemisphere, followed by cognitive impairment, often lead to changes in brain networks, affecting both hemispheres [2, 4]. That is perfectly understandable, since both hemispheres are involved in realization of any cognitive function, however, parts, played by the right and the left hemisphere, may vary considerably. That is why interhemispheric communication assumes particular importance, which has been confirmed by our findings. This fact has been noted in some other papers. In particular, it has been shown, that reduced default mode network and frontoparietal networks connectivity correlates with lower verbal fluency and delayed recall scores [17].

The sample of patients with CCI, assessed using fMRI, was smaller compared to the sample of patients, assessed using duplex ultrasonography and psychological testing only. Nevertheless, this does not impose any serious restrictions on the interpretation of the results. The sample of subjects assessed using fMRI (55 patients with CCI) is to be considered representative: the patients were randomly selected; they did not differ in average RI values and psychological test scores. There is no reason to believe that two discussed above samples could reflect different patterns.

In general, juxtaposing the hemodynamic parameters of the major arteries of the head and the characteristics of fMRI BOLD signals is promising in terms of studying the pathogenesis of vascular diseases.

CONCLUSIONS

The left ICA resistive index (RI) correlates with preserved cognitive functions in patients with CCI. The left ICA RI below 0.55–0.54 corresponds to a more successful realization of verbal cognitive functions. Variation of the right ICA RI does not correlate with the characteristics of verbal cognitive functions. The left ICA RI correlates with differences in the organization of the brain networks: low, normal physiologival RI values correspond to the better presented interhemispheric connections in the cerebral cortex, basal ganglia, and brainstem. High RI values correspond to higher connectivity between frontal and occipital cortical regions, as well as with cerebellum. In patients with CCI, the left ICA RI can be considered as a biomarker of cognitive decline and brain networks reorganization.

PLASMA LOW MOLECULAR WEIGHT AMINOTHIOLS IN ISCHEMIC STROKE PATIENTS WITH TYPE 2 DIABETES MELLITUS

Maksimova MYu, Ivanov AV, Nikiforova KA, Virus ED, Suanova ET, Ochtova FR, Piradov MA, Kubatiev AA

1 Research Center of Neurology, Moscow, Russia
2 Research Institute of General Pathology and Pathophysiology, Moscow, Russia
3 Evdokimov Moscow State University of Medicine and Dentistry, Moscow, Russia

It was found that ischemic stroke (IS) results in decreased levels of a number of reduced forms of low molecular weight aminothiols (LMWTs). The study was aimed to assess the impact of type 2 diabetes mellitus (T2D) on the total content, reduced forms and redox status of LMWTs in patients with IS. A total of 175 patients with IS in the internal carotid artery basin (the average age was 65 (55–69) years) were assessed, who were admitted to the Center within the first 10–24 h since the onset of neurological disorder. The index group included 68 patients with IS and T2D (males made up 41.2%). The comparison group consisted of 107 patients with IS and stress hyperglycemia (males made up 54.8%). The admission plasma levels of LMWTs were assessed by liquid chromatography in all patients. It was found, that IS in patients with T2D was associated with the rapid decrease in total cysteine (tCys), total glutathione (tGSH), total homocysteine (tHcy), reduced glutathione (rGSH), and glutathione redox status (GSH RS), along with the increase in cysteine redox status (Cys RS) and homocysteine redox status (Hcy RS). In contrast to patients with stress hyperglycemia developing during the acute period of IS, patients with T2D had lower tCys, tGSH, and tHcy levels. Thus, GSH RS of 4.06% or lower in the first 24 hours after the IS in patients with T2D was a predictor of poor functional outcome (mRS score was 3 or more 3 weeks after IS).

Keywords: ischemic stroke, type 2 diabetes mellitus, low molecular weight aminothiols

Author contribution: Maksimova MYu — concept formulation, data synthesis, manuscript writing; Ivanov AV — concept formulation, literature analysis, assessment of low molecular weight aminothiols; Nikiforova KA — primary laboratory data acquisition; Virus ED — laboratory data synthesis; Suanova ET — statistical data processing; Ochtova FR — clinical assessment of patients; Piradov MA — study management; Kubatiev AA — study management.

Compliance with ethical standards: The study was approved by the Ethics Committee of the Research Center of Neurology (protocol № 3-1/16 dated March 16, 2016). It was carried out in accordance with the basic principles outlined in the Declaration of Helsinki.

Установлено, что ишемический инсульт (ИИ) приводит к снижению ряда восстановленных форм низкомолекулярных аминотиолов (НМАТ). Целью исследования было оценить влияние сахарного диабета 2-го типа (Т2Д) на общее содержание, восстановленные формы и редокс статус НМАТ у пациентов с ИИ. Обследовано 175 пациентов с ИИ в бассейне внутренних сонных артерий (средний возраст 65 (55–69) года, поступившие в центр в первые 10–24 ч с момента возникновения неврологических нарушений. В основную группу вошли 68 пациентов (41,2% мужчин) с ИИ и Т2Д. Группу сравнения составили 107 пациентов (57% мужчин) с ИИ и стрессовой гипергликемией, контрольную группу — 31 пациент (54,8% мужчин) с хронической гипертрофической кардиомиопатией (ДГКП) без СД. Во всех случаях пациентам при поступлении проводили исследование НМАТ в плазме крови методом жидкостной хроматографии. Установлено, что ИИ у пациентов с Т2Д сопровождается с резким снижением уровня общего цистеина (оЦис), общего глутатиона (оГлн), общего гомоцистеина (оГцис), восстановленного глутатиона (РСГлн), редокс-статуса глутатиона (РСГлн), а также повышенным редокс-статусом цистеина (РСЦис) и редокс-статусом гомоцистеина (РСГцис). У пациентов с Т2Д, в отличие от пациентов с развитием стрессовой гипергликемии в остром периоде ИИ, отмечено более низкое показатели оЦис, оГлн и оГцис. Таким образом, уровень РСГлн, составляющий 4,06% и более в первые сутки ИИ у пациентов с Т2Д, является предиктором неблагоприятного функционального прогноза (оценка по шкале mRS составляет 3 балла и более спустя 3 недели после ИИ).

DOI: 10.24075/vrnu.2021.057
Stroke is a major cause of morbidity, disability and mortality in the populations of many countries. Type 2 diabetes mellitus (T2D) increases the risk of ischemic stroke (IS) by 2–2.5 times, and the risk of death from stroke by 3 times [1, 2]. Hyperglycemia during the first hour of stroke could be the body’s stress response to brain ischemia [3]. Severity of neurohormonal and metabolic disorder reflects the IS severity and contributes to the outcome of the disease [4].

High prevalence of the internal carotid artery (ICA) atherosclerosis in patients with T2D compared to non-diabetic patients has been reported. That is why atherothrombotic stroke is the most common IS pathogenetic subtype in individuals with T2D [5].

Oxidative stress is one of the key factors involved in the pathogenesis of IS. Accumulation of free radical oxidation products results in the enzyme SH group blockage and inactivation, DNA hydroxylation, DNA fragmentation, and the resulting destabilization of cell membranes [6, 7].

Low molecular weight aminothiols (LMWTs) are highly sensitive to oxidative stress. Oxidized forms of LMWTs predominates in blood plasma; redox status (RS) is the ratio between the reduced forms and the total content of each thiol. Experimental studies and clinical trials report the decrease in the levels of reduced forms during the acute period of IS, which could indicate activation of oxidative processes in case of insufficient antioxidant defence [8, 9].

Both the increase in total homocysteine content (tHcy) and the decrease in the total glutathione content (tGSH) in females were revealed in patients with T2D [10]. Other papers report the decreased glutathione redox status (GSH RS) in blood plasma [11] and whole blood [12] of patients with T2D. Negative correlation between hyperglycemia and plasma tGSH levels was observed in individuals with coronary artery disease (CAD), \( r = -0.328, \rho = 0.011 \), furthermore, it was shown that T2D was a factor, having an additional negative effect on the tGSH levels [13]. Perhaps low plasma tGSH levels are associated with the increased activity of \( \gamma \)-glutamylcysteine transferase in hyperglycemia [10]. The decreased GSH synthesis along with the possible increase in GSH consumption in red blood cells of patients with T2D were also reported [14].

The study was aimed to assess the impact of T2D on the total content (t), reduced forms (r) and RS of plasma LMWTs in patients with IS.

METHODS

The study included 175 patients with IS in the ICA basin (89 males and 86 females aged 46–84 (the average age was 62 (55–69 years)), admitted to the Research Center of Neurology (Moscow; Russia) within the first 10–24 h since the onset of the neurological disorder. The index group consisted of 68 patients with IS and T2D (males made up 41.2%). The comparison group included 107 patients with IS and stress hyperglycemia (males made up 57%), and the control group consisted of 31 non-diabetic patients with chronic cerebrovascular disease (CCVD) (males made up 54.8%, the average age was 69 (60–75) years).

Inclusion criteria: age 45–85 years; the first IS; admission within the first 6–24 h since the onset of neurological symptoms; cerebral infarction in the ICA basin confirmed by neuroimaging data; T2D or stress hyperglycemia on admission; submitted informed consent to participation in the research study.

Exclusion criteria: T1D; acute myocardial infarction; decompensated kidney disease, liver failure or respiratory failure; class III–IV heart failure. General medical examination and neurological examination were performed in all patients.

The neurological impairment severity was assessed on admission and in the end of the IS acute period using the National Institutes of Health Stroke Scale (NIHSS) [15]. Neurological impairment was considered mild when NIHSS < 7, moderate when 7 ≤ NIHSS < 14, and severe stroke when 14 ≤ NIHSS. The activities in daily living and the ability to function independently were evaluated on admission and on day 21 of IS using the Barthel Index (BI) [16], and the functional status was assessed with the use of the modified Rankin scale (mRs). The ability to perform all the routine tasks and to be engaged in daily activities corresponded to the mRs score of 0–2 by day 21, and poor functional outcome corresponded to the score of ≥ 3 [17].

IS was diagnosed based on the clinical features and magnetic resonance imaging data (Magnetom Symphony and Magneton Avanto, 1.5 T) acquired using standard sequences (T2, T1, T2-FLAIR, T2*). Cerebral arteries were examined by 3D TOF MR angiography. Duplex ultrasonography of the cerebral arteries was performed using the Philips iU22 ultrasound system (Philips; Netherlands).

Pathogenetic subtype of IS was defined in accordance with the internationally accepted TOAST (Trial of ORG 10172 in Acute Stroke Treatment) criteria [18].

Fibrinogen assay was carried out with the ACL 9000 coagulation analyzer (Instrumentation Laboratory; USA).

Glucose (hexokinase method), glycated hemoglobin (HbA1c) (immunoturbidimetric assay), total cholesterol, low-density lipoprotein, urea, and creatinine levels were assessed with the Konelab 30 clinical chemistry analyzer (Thermo Fisher Scientific; Finland) using the reagent kits (Randox; UK).

All patients with IS underwent blood glucose monitoring on admission. The HbA1c test was performed on patients with admission blood glucose levels of 6.1 mmol/L or more. The HbA1c levels reflect the blood glucose levels over the last 3 months. The diagnosis of T2D was established based on the American Diabetes Association criteria [19].

All patients with IS received backbone therapy, which included hypotensive, antithrombotic and lipid-lowering agents. Glucose-lowering therapy was used along with the blood glucose monitoring.

The content of LMWTs was defined as described previously [8]. Venous blood was collected into tubes containing sodium citrate (0.38%) and centrifuged at 3,000 g for 3 min. Blood plasma for assessment of total LMWTs was collected and stored at –20 °C. For derivatization, 100 μL of blood plasma were added to 10 μL of 50 mM dithiotreitol and 10 μL of the internal standard (0.45 mM penicillamine). Dithiothreitol and penicillamine solutions contained 10 mM Na-EDTA. The mixture was incubated at 37 °C for 15 min. Subsequently, the 5,5’-dithiobisnitrobenzonic acid (600 μL, 20 mM) dissolved in ethanol was added, and the mixture was incubated at 4 °C for 30 min. After centrifugation at 15 000 g for 5 min, supernatant was dried under a vacuum at 60 °C for 2 h. The pellet was resuspended in 30 mM NaOH prior to analysis.

To define the levels of the LMWTs reduced forms, plasma (100 μL) was added to 25 μL of the 5-sulfosalicylic acid solution (230 g/L) immediately after plasma collection, frozen and stored at –80 °C. The samples were centrifuged at 15,000 g for 5 min prior to derivatization. Subsequently, 40 μL of supernatant were mixed with 40 μL of 20 mM 5,5’-dithiobisnitrobenzonic acid and 2.5 μM penicillamine in 0.4 M sodium phosphate buffer (pH 8.0). Then 10 μL of 1 M NaOH were added, the solution was mixed for 5 s, and subsequently 12.5 μL of 1 M HCl with 20 mM N-ethylmaleimide were added to quench the reaction.

The study was aimed to assess the impact of T2D on the total content (t), reduced forms (r) and RS of plasma LMWTs in patients with IS.
Analysis was performed using the Waters ACQUITY UPLC system (Waters, Milford; USA), equipped with the photodiode array (LPDA) UV detector (absorbance 330 nm; resolution 10.8 nm; frequency 5 s−1) and the Poroshell 120 SBC18 column (2.8 μm, 150 μm × 2 mm) (Agilent; USA). The temperature of the column and samples of 50 and 10 °C, respectively, was maintained. The volume of the sample injection was 10 μL, and the flow rate was 0.2 mL/min. Eluent A: 0.1 M ammonium acetate with 0.12% (v/v) HCOOH; eluent B: acetonitrile. Chromatography involved gradient elution using a linear gradient of solvent B of 2.5–10% for 5 min. Regeneration was performed with the use of 70% B for 1.5 min, and equilibration was carried out using 2.5% B for 4 min.

Statistical data processing was performed with the IBM SPSS Statistics Version 20.0 software package (IBM Corp.; USA). The Descriptive Statistics module was used to obtain the discriminative model. The quantitative characteristics were presented as median, 25th and 75th percentiles (Ме (Q1–Q3)), qualitative data were presented as absolute frequencies and percentage. The Kruskal–Wallis test and Mann–Whitney U test were used to compare the groups based on their quantitative characteristics. The logistic regression procedures were used to identify the prognostic factors. The variables were selected by conditional inclusion. The quality of the logistic regression model was assessed by ROC analysis and calculation of statistical characteristics of the tests (sensitivity, specificity). To evaluate the predictive power of the model, the Area Under Curve (AUC) was assessed. To define the optimal cutoff value, the importance of maintaining the sensitivity-specificity balance was taken into account. The two-tailed critical p-value, used in all comparisons and tests, was set at 0.05.

RESULTS

The main characteristics of patients with IS and CCVD are presented in Table 1. The groups of patients showed no differences in age, gender, and indicators of lipid and protein metabolism. The patients with IS had been constantly taking antihypertensive drugs in 46 cases (26.3%), antiplatelet drugs in 22 cases (12.6%), anticoagulants in 11 cases (6.3%), and statins in 8 cases (4.6%) before being included in the study. The group with CCVD received no preventive therapy before inclusion in the study.

Stroke, caused by the ICA atherothrombosis, was diagnosed in 55 cases (20%), cardioembolic stroke was diagnosed in 50 cases (28.6%), and lacunar stroke due to small-artery disease was diagnosed in 90 cases (51.4%).

In patients with atherothrombotic stroke, the developing step-by-step neurological deficits and the occurrence of single large infarctions affecting the cortical and subcortical regions outside the neighboring vascular territories were observed.

The heart-related causes of the cerebral artery thrombosis were as follows: embolicogonic forms of CAD (paroxysmal atrial fibrillation in 29 cases (58%), permanent atrial fibrillation in 17 cases (34%), postinfarction cardiiosclerosis in 4 cases (8%)). In 34 patients, atrial fibrillation was diagnosed for the first time during the acute period of IS. Sudden emergence of persistent neurological symptoms was a clinical feature typical for cardioembolic stroke. Based on the MRI data, the cortical and subcortical infarctions were localized mostly in the middle cerebral artery basin.

IS, resulting from the hypertensive, small, deep cerebral infarctions, was characterised by the gradually increasing...
intensity of neurological deficits in the form of lacunar syndromes. Small, deep cerebral infarctions were localized in the basal ganglia, white matter of cerebral hemispheres, and internal capsule. Stage III hypertension was found in 71 patients (78.9%) with lacunar stroke, and stage II hypertension was observed in 19 patients (21.1%).

The baseline IS severity assessment made it possible to reveal mild neurological impairment (NIHSS < 7) in 92 cases (52.6%), moderate neurological impairment (7 ≤ NIHSS < 14) in 67 cases (38.3%), and severe neurological impairment (14 ≤ NIHSS) in 16 cases (9.1%) (see Table 1).

The admission blood glucose level in patients with IS was 6.50 (6.22–7.72) mmol/L.

Analysis of LMWTs showed that the tGSH, rGSH, and GSH RS levels in the group with IS were significantly decreased (r < 0.0001), and the rHcy and Hcy RS values were significantly increased (p = 0.018 and p = 0.041) compared to the group with CCVD (Table 2).

Analysis of the total sample revealed higher rHcy values in males with RS compared to females (0.17 (0.14–0.24) μM vs. 0.15 (0.12–0.21) μM; p = 0.026).

In the group of IS patients enrolled, T2D was diagnosed in 68 cases, and stress hyperglycemia was diagnosed in 107 cases (Table 3). The duration of T2D of less than 5 years was observed in 22 patients (32.4%), and the disease duration exceeding 5 years was observed in 46 patients (67.6%). In the group of patients with a combination of IS and T2D, the HbA1c level was 7.8% (6.8–9.6). The levels of less than 6.5% were defined in 107 patients (61.1%), the levels of 6.5–6.9% were found in 32 patients (18.3%), 20 patients (11.4%) had the levels exceeding 7%.

</table>
HbA1c levels of 7–7.9%, and the levels exceeding 8% were found in 16 patients (9.2%).

Stroke, resulting from cerebral artery thrombosis with a cardiac source of embolism, was more common in patients with T2D (p < 0.0001), and atherothrombotic stroke was more common in patients with stress hyperglycemia (p < 0.0001). No intergroup differences in the prevalence of lacunar stroke were found (p = 0.162). The examined groups of patients were comparable in the neurological impairment severity and their functional status during the acute period of stroke (see Table 3).

In the group of patients with a combination of IS and T2D, the significantly decreased tCys, tGSH, and tHcy levels were observed compared to the group of patients with IS and stress hyperglycemia (p < 0.0001). However, there were no significant differences in the rCys, rGSH, and rHcy levels between the groups of patients with T2D and stress hyperglycemia. Probably, this entails higher Cys RS, GSH RS, and Hcy RS differences in the rCys, rGSH, and rHcy levels between the groups of patients with T2D and stress hyperglycemia. This is presented in Fig. 1. ROC analysis of 68 patients with IS in the ICA basin and T2D showed that the threshold level GSH RS ≤ 4.06% during the first 24 h of IS is a predictor of poor IS outcome (mRS ≥ 3, 21 days after IS). Sensitivity of the model was 63.6%, specificity was 69.6%, and AUC was 0.74 ± 0.09, which corresponds to the good quality in predicting the functional recovery in patients with IS.

**DISCUSSION**

Chronic hyperglycemia, associated with T2D, is considered one of the risk factors for IS. Glucose is a chemical compound, which actively interacts with proteins and lipids, forming the advanced glycation end products [20, 21]. Hyperglycemia, chronic oxidative stress, and mitochondrial dysfunction, associated with T2D, result in endothelial dysfunction, impaired angiogenesis, activation of hemostasis, and the increased blood-brain barrier permeability [22]. Hyperglycemia enhances oxidative processes by lowering the levels of vitamins E, C, and other antioxidants (uric acid) [11], it is also an additional factor that stimulates and facilitates the reactive oxygen species formation [23].

In individuals with IS, the effects of hyperglycemia on the brain are mediated by both impaired cerebral microcirculation, and the toxic effects on brain tissue. Lactate accumulation, free radical formation, development of cytotoxic cerebral edema, and abnormal blood-brain barrier permeability are attributed to hyperglycemia [25, 26].
Hyperglycemia in individuals with T2D and IS results in depletion of the antioxidant system and disorders of all types of tissue metabolism. The thiol/disulfide ratio (SH/SS) is the indicator of cellular and tissue redox homeostasis, as well as of the blood plasma antioxidant capacity [11, 27].

Glutathione is an endogenous thiol tripeptide, composed of cysteine, glutamic acid, and glycine. It is being synthesized continuously, but at a relatively low rate [28]. Glutathione is also a factor involved in regulation of glucose metabolism in patients with cardiovascular disorders [13]. Polymorphism of glutathione S-transferase, the enzyme, involved in the glutathione-mediated detoxification of xenobiotics, contributes to the early cardiovascular complications of diabetes mellitus [29].

In individuals with acute oxidative stress, the total content of glutathione (GSH) is decreased, and the levels of oxidized glutathione (GSSG) are increased, which results in the accelerated GSH/GSSG cycle [27].

Hyperglycemia during the acute period of IS is associated with poor functional outcome [4], however, the efficacy of insulin-based glucose lowering therapy and its effects on the severity and outcome of stroke have not been proven [1].

The findings show that T2D in patients with IS is associated with the rapid decrease in plasma tCys, tGSH, tHcy, rGSH, and GSH RS, along with the increase in Cys RS and Hcy RS.

Perhaps the chronic oxidative stress results in depletion of LMWTs in blood plasma. Irreversible disposal of GSH may be associated with intense oxidative stress, when GSH is exported from cells in order to prevent the significant shift in the redox equilibrium [28]. Presumably, it is the main mechanism explaining the lack of correlations between tGSH, tCys and tHcy, as well as between tGSH and rGSH. No significant correlations between plasma glucose levels and LMWTs have been revealed. This indicates that alterations in the metabolism of LMWTs associated with T2D are mediated by non-glycemic mechanisms.

The GSH RS value of 4.06% or lower during the first 24 h of IS is a predictor of poor IS outcome (mRS ≥ 3, three weeks after IS). Therefore, the search for approaches to glutathione metabolism correction in patients with T2D may be regarded as the potential therapeutic objective during the acute period of IS.

CONCLUSIONS

T2D is a factor having a major impact on the metabolism of LMWTs in patients with IS. Regardless of the lack of correlations between the glucose levels and LMWTs, T2D was associated with reduced total content of homocysteine, cysteine and glutathione, and the glutathione redox status of 4.06% or lower during the first 24 h of IS was associated with poor functional outcome. Glutathione metabolism correction in individuals with a combination of IS and T2D may have a positive impact on the course of IS.

References

Balance impairment at advanced age is a serious medical problem that often has significant implications and affects the quality of the patient’s life. Among the underlying causes are overall slowness of motor response and vestibular syndrome. Virtual reality exergames, including reaction and balance training, hold promise for managing balance dysfunction. The aim of this study was to investigate the effects of a combination rehabilitation program containing elements of virtual reality exergame on the postural and psychophysiological parameters of elderly patients with small vascular disease. The study was conducted in 24 patients with small vascular disease (median age: 66 years). All patients underwent a virtual reality rehabilitation program. Psychophysiological, postural, and clinical evaluations were performed at baseline and after the program was completed. Balance function measured on the Berg scale improved significantly and was 53 [52; 55] after the training program vs 50 [45; 54] at baseline (p < 0.05). The strategy of balance control also changed: the Romberg ratio was 266 [199.5; 478.5] before rehabilitation and 221 [149.25; 404] after the program was completed (p < 0.06). The most pronounced changes in the measured psychophysiological parameters occurred in the simple audiotor motor reaction, which improved from 210 [174.25; 245.5] at baseline to 180.5 [170.5; 208] after rehabilitation (p < 0.05). Thus, the combination balance and reaction virtual reality training is an effective rehabilitation method for advanced-age patients with balance impairment.

Motor and balance dysfunction is the primary cause of increased risk for falling at advanced age. More than one-third of elderly people over 60 years have a gait disturbance. At 60–69 years, the prevalence of gait disorders is about 10.7%, increasing to 61.7% in 80-year-old patients. Gait disturbances are rooted in neurological causes in 75% of cases [1]. Among the leading causes of motor dysfunction are sensory ataxia, parkinsonism, brain damage, and cerebrovascular diseases such as small vessel disease [2]. The latter usually manifests as gait disturbance (in up to 85% of patients with stage 2 small vessel disease), pyramidal disorders, akinetic rigid syndrome, loss of coordination, including declining ability to maintain balance, etc. [3].

The slowness of postural response to external stimuli is one of the factors affecting balance at advancing age. It is difficult for elderly patients to adequately cope with an unexpected balance disturbance; they typically respond with increased muscle coactivation and joint stiffening, which cannot ensure effective amortization [4]. In another study, elderly patients demonstrated a slow motor response when asked to lift a foot following a visual cue, and often shifted their body weight in preparation for a step. The difference in reaction times between the groups waned when the preparation stage was excluded from the analysis. Thus, a slow motor response may be associated not only with overall slowness but also with incorrect preparation to movement [5]. Apart from longer reaction time, postural stability is affected by slow braking. In an experiment involving a series of forward and backward movements, elderly participants demonstrated a higher forward velocity (2nd movement) to compensate for overall motor slowness. Besides,
their strategy of movement control was different from that of the young participants, and the braking process took longer. The authors concluded that attempts to adapt to overall motor slowness may lead to increased postural instability [6].

The risk of falls can be prevented or reduced through rehabilitation programs. Over the past two decades, a variety of high-tech methods have been introduced into routine rehabilitation. A substantial body of evidence has been accumulated confirming the effectiveness of robotic technologies, exoskeletons, brain-computer interfaces, non-invasive methods for brain stimulation, etc. [7–12]. In the age of technological abundance, a personalized approach to rehabilitation and the search for predictors of effectiveness of the applied technology and rehabilitation as such are becoming increasingly important [13]. In this light, it would be useful to identify methods for determining the effectiveness of the chosen rehabilitation approach for an individual patient. The aim of this study was to evaluate effects of the integrated rehabilitation program for better balance and faster motor response on postural and psychophysiological parameters.

METHODS

The study was conducted in 24 patients with small vascular disease (5 men and 19 women). The median age was 66 years (61; 72).

The following inclusion criteria were applied: patients of both sexes aged 60 to 70 years with Small vessel disease. Exclusion criteria: severe visual impairment preventing the patients from discriminating images on the screen; severe cognitive impairment preventing the patients from following the instructions; Montreal Cognitive Assessment (MoCA) score < 26 point; visual or motor impairments or non-morbidities causing static and dynamic balance impairments.

The patients underwent rehabilitation on a virtual reality Rehabunculus system (Intelligence and Innovations; Russia) fitted with a non-contact Kinect sensor (Microsoft; USA).

The rehabilitation course lasted for 10 days and comprised 5 30-min-long sessions per week. Exercises included in the course aimed at training static and dynamic balance function and the speed of motor reaction (Darts, Stepping over the course aimed at training static and dynamic balance function) as quickly as possible in response to a certain combination of colors (CVMR-CC). The patient was tasked to press Yes or No as quickly as possible in response to a certain combination of 3 flashing light stimuli (green leftmost light, red rightmost light).

5. A complex visuomotor reaction to a combination of colors (CVMR-CC). The patient was tasked to press Yes or No as quickly as possible in response to a certain combination of 3 flashing light stimuli (green leftmost light, red rightmost light).

6. A functional activity of nervous processes test (FMNP). The patient was tasked to press Yes or No as quickly as possible in response to a rapidly flashing light (red light — yes, green light or skipped yellow light — no).

7. A reaction to a moving object test (RMO). The patient was tasked to press Yes or No with their dominant hand to stop the pointer indicator before it reached the target position (indicated by the flashing light).

The total duration of psychophysiological testing was 30 min. Prior to each test, the patients received the instructions and verbally confirmed that the instructions were understood. The patients put their fingers in a comfortable position above the console. The stimuli were delivered at different time intervals to exclude the possibility of adjusting.

Static and dynamic balance at baseline and after the rehabilitation course was measured using a Stabilan-01-2 system (RITM OKB; Russia) and the Berg balance scale [15].

The obtained data were processed in Statistica v. 7.0 (StatSoft; USA) using the Mann–Whitney U test for independent samples, Wilcoxon test for dependent samples, and Spearman’s correlation coefficient. The results are presented below as medians and lower and upper quartiles (25%, 75%). Differences were considered significant at \( p < 0.05 \).

RESULTS

Effects of virtual reality training on balance function in elderly patients

The median Berg score was 50 [45; 54] points at baseline, increasing by 3 \(( p < 0.05)\) points after the rehabilitation course and thus reaching 53 [52; 55] points. The baseline Berg score was negatively correlated with the Berg score after rehabilitation (the correlation coefficient was 0.823 at \( p = 0.000005 \)).

Body sway was analyzed using standard parameters listed in Table 1.

After the rehabilitation course, the Romberg ratio (KoeffRom) was significantly lower \(( p < 0.05)\) than at baseline (Fig. 1); there was a significant increase in the LFS value (length to area ratio in the eyes-closed test) and the strength of correlation between COP position in the sagittal plane relative to the line connecting the lateral and medial malleoli and COP velocity in the eyes-open test (VFY.o).

The eyes-open test revealed a significant \(( p < 0.05)\) increase (in comparison with baseline values) in the mean COP velocity \(( V_o \)) in the normalized vectorgram area \(( AV_o \)) increase in the mean linear velocity \(( MLV_o \)) especially in the sagittal plane \(( MLV_o_sag)\), a trend increasing in the COP excursion index \(( OD_c; p = 0.055)\) and in the normalized vectorgram length on the X axis \(( LX_o; p = 0.058)\).

</table>

The stability test revealed a significant ($p < 0.05$) increase in SZone (Fig. 2), an increase in frontal displacement (MO) ($p < 0.01$), an increase in the mean COP displacement radius (R), an increase in the mean COP velocity (V), an increase in the rate of statokinesigram area change (SV), an increase in the velocity index (IV), a reduction in the coefficient of displacement asymmetry in the frontal plane (KAssM(x)), an increase in the mean linear velocity (MLV), and an increase in the total angle of vector displacement (TAD_c).

Effects of virtual reality training on psychophysiological parameters in elderly patients

The simple visuomotor response test showed a trending decrease ($p = 0.052$) in the average reaction time (SVMR_MO) and a trending reduction ($p = 0.061$) in the squared deviation of the reaction time (SVMR_SD). According to the statistical analysis, there was a trending increase ($p = 0.069$) in the error rate, which is below referred to as the integrated reliability index (SVMR_IRI) after the training program.

The complex visuomotor response test revealed a significant ($p < 0.05$) increase in sensorimotor performance (CVMR_CNSAL), quantitative CNS activation index (CVMR_P) and reaction time mode amplitude representing the percentage of the shortest reaction times (CVMR_AMODA).

The test of the simple visuomotor reaction to the movement of the pointer indicator demonstrated a trending increase ($p = 0.053$) in the integrated reliability index after the training course (SVMR_IM_IRI).

Changes were the most pronounced for the simple audiomotor reaction ($p < 0.05$): there was an increase in the integral reliability index (SAMR_IRI), a reduction in the mean...
reaction time (SAMR_MO) (Fig. 3) and a reduction in the median value (SAMR_Me).

The reaction to a moving object test conducted after the training course demonstrated a significant ($p < 0.01$) rise in the number (RMO_NS) and percentage (RMO_PS) of successes and a reduction in the number (RMO_ND) and percentage (RMO_PD) of delays (Table 2).

No significant differences were observed between the results of the tests evaluating the complex visuomotor reaction to a combination of colors and the functional activity of nervous processes at baseline and after training.

The correlation analysis showed that the initial number and percentage of delayed RMO were positively correlated with changes the angular velocity asymmetry coefficient ($r = 0.53; p < 0.05$) and total angular displacement ($r = 0.57; p < 0.05$) measured in the Romberg eyes-closed test. This indicates that patients with initially slower response to a moving object had to adjust their COP position to maintain their balance more frequently and to a greater extent.

Changes in the Berg score were significantly ($p < 0.05$) correlated with the baseline integrated reliability index in the SAMR test (SAMR_IRI), CNS activation level (SAMR_CNSAL), quantitative CNS activation index (SAMR_QCNSAI), number of the classification square (SAMR_CSN), mean SAMR time (SAMR_MO), quickness of response (SAMR_QR), quickness of response in relative units (SAMR_QRR), mean squared deviation of speed (SAMR_MSD), median SAMR time (SAMR_Me), SAMR time mode (SAMR_Mo), and the longest SAMR time (SAMR_MaxT) (Table 3).

These correlations may be explained by the fact that the most pronounced changes on the Berg scale were observed in patients with the worst baseline balance parameters; according
to the SAMR test, the initial functional CNS state was also worse in these patients.

No correlations were established between the changes in the psychophysiological parameters and sway dynamics in the Romberg and stability tests.

The change in the Berg score was significantly \((p < 0.05)\) correlated with the SAMR_IRI value \((r = 0.72; p < 0.05)\), changes in the mean reaction time \((r = -0.73, p < 0.05)\) and the SAMR median \((r = -0.69; p < 0.05)\).

**DISCUSSION**

Based on the dynamics of the Romberg ratio, we conclude that after the rehabilitation course the patients were guided less by their vision and more by their proprioception to maintain balance. This can be explained by the necessity to use biological feedback in the virtual reality environment, which required that the patients compared proprioceptive inputs with the current position of their COP projected on the screen. The 3-D avatar on the screen allowed the patient to use the horizon in the virtual reality environment as a feedback source and to improve proprioception.

The increase in statokinesigram density \((LFS_c)\) indicates a higher density of COP positions within a smaller area, suggesting an improvement in balance function. The correlation between COP positions in the sagittal plane relative to the line connecting the lateral and medial malleoli and COP velocity \((VFY)\) changed from negative to positive, suggesting a change in the balance control strategy. The positive values indicate a reduction in triceps surae muscle tension and a forward COP displacement, which is a sign of a more physiologically sound strategy for balance control.

The increased values of various velocity parameters in the Romberg test may be linked to a reduction in rigidity and adoption of a more robust balance control strategy instead of a compensatory one. Giving up the compensatory strategy is essential for gaining the sufficient degree of freedom for COP movement needed to improve balance. As seen from the results of the stability test, motor control significantly improved after the rehabilitation course; the velocity and magnitude of COP excursions were much greater and easier to achieve after the course \([16, 17]\).

The higher Berg score after the rehabilitation program suggests an improvement in the static, dynamic and functional balance. The patients with the worst balance parameters at baseline made the greatest progress during the course. Thus, the proposed 10-day rehabilitation program had a positive impact on balance function in patients with small vascular disease, which is consistent with the findings of other studies \([18-20]\) and corroborates the effectiveness of virtual reality as a tool for balance training \([21]\).

The applied psychophysiological tests demonstrated that VR-based rehabilitation led to a reduction in mean SAMR and SVMR times and an increase in the integrated reliability index. The latter estimates the percentage of errors for each response. It is calculated as a mean of the reliability coefficients \((RC1)\) for each response. No rehabilitation-related improvement in response times was registered during complex sensorimotor response tests, but the number of different error types became lower and the functional state of CNS improved.

Complex sensorimotor reactions studied in the experiment were represented by recognition and choice behaviors. Not all of the applied tests revealed statistically significant changes after the rehabilitation course: changes were not while testing

the functional activity of nervous processes and the complex visuomotor reaction to a combination of colors. Perhaps, this may be due to the fact that these tests were the most difficult and required involvement of substantial cognitive resources. Overall, improved reaction time after the rehabilitation program is consistent with the literature data [22–24]. However, some researchers report slower reaction times [25] while others do not detect any effect of training on the quickness of motor response [26]. To our knowledge, there has been no analysis of correlations between VR-based rehabilitation and the reliability of testing, erroneous responses and other similar parameters. This is probably due to the choice of the device used for psychophysiological testing.

The patients with the best progress on the Berg scale (i.e., those who had worse results at baseline) also demonstrated a greater improvement in SAMR IRI, mean SAMR speed and median. This suggests that the VR-based rehabilitation program is effective in improving both balance and cognitive functions and demonstrates a predictive value of the SAMR test. The integrated reliability index and the mean SAMR speed allow identification of patients with initially worse parameters who may benefit the most from VR-based rehabilitation.

It is known that balance control depends on the afferent integration of visual, vestibular and proprioceptive inputs. Although the auditory system provides the patient with accurate and precise spatial reference, its auxiliary role in balance control is not acknowledged [27]. Nevertheless, some authors hypothesize that the role of auditory stimuli may increase if one of other involved systems is impaired [28]. The established correlation between changes in audiomotor response speed and the dynamics of balance function after rehabilitation may be linked to the increased role of auditory afferentation associated with changes in the compensatory strategy.

So far, no reliable predictors of motor recovery have been identified; however, the SAMR test may be a potential candidate. Perhaps, the absence of a unified predictor in our study may be linked to the diversity of balance impairment mechanisms in the included patients. Besides cognitive impairment, balance disorders can be caused by sarcopenia, motor deficit, proprioceptive disorders, etc.

Further research should be conducted on a larger patient sample; subgroups should be formed based on the cause of balance impairment. Larger patient samples and the analysis of vestibular function accounting for the physiological characteristics of study participants will allow us to identify different patterns of balance impairment and develop a working tool for determining therapeutic targets in balance training.

CONCLUSIONS

Based on the preliminary results, we conclude that 1) balance impairment in elderly patients may be associated with both CNS activation and inhibition impairments and postural or motor disorders; 2) a combination balance and reaction virtual reality training is an effective rehabilitation method for elderly patients that improves static and dynamic balance control; the training program helps the patient to give up the compensatory strategy and adopt a new, more physiologically robust one (in terms of biomechanics); 3) virtual reality-based balance training improves balance control and CNS activation and stimulates the patient to use additional afferent sources for balance control; 4) patients with initially more pronounced balance disorders make better progress in improving the accuracy and speed of response to visual and auditory cues during the program. Thus, the combination balance and reaction virtual reality training has a potential to become an effective rehabilitation method. However, in order to identify reliable psychophysiological and stabilemetric predictors of its effectiveness, further research is needed involving patient grouping by the cause and degree of balance impairment.

ULTRASOUND IMAGING OF VAGUS NERVES IN PATIENTS WITH PARKINSON’S DISEASE

Chechetkin AO, Moskalenko AN, Fedotova EYu, Illarioshkin SN

Research Center of Neurology, Moscow, Russia

Parkinson’s disease (PD) is a neurodegenerative multisystem disorder characterized by pathologic α-synuclein aggregation affecting, among other things, vagal fibers. The aim of this study was to investigate the cross-sectional area (CSA) of the vagus nerve (VN) in patients with PD using ultrasound imaging. The study was conducted in 32 patients with PD (15 men and 17 women; mean age 58 ± 10 years) and 32 healthy controls comparable with the main group in terms of sex and age. All study participants underwent ultrasound examination of the VN using a high-resolution transducer. Left VN CSA was significantly smaller in patients with PD than in the control group (1.78 ± 0.52 mm² vs 2.11 ± 0.41 mm²; p = 0.007). A similar result was obtained for right VN CSA at the trend level. ROC analysis demonstrated that the threshold CSA value of < 2.10 mm² for the left VN has low diagnostic sensitivity (59%) for VN atrophy in patients with PD. Right VN CSA was significantly larger than left VN CSA in both groups (p < 0.001). The analysis of the PD group did not reveal any associations between VN CSA and age, duration and stage of the disease, motor (UPDRS III) and non-motor (NMSQ) scores. Patients with akinetic-rigid form of PD had smaller left VN CSA than patients with the mixed form of the disease (p < 0.05). A moderate inverse correlation was established between left VN CSA and the area of substantia nigra hyperechogenicity on both sides (p < 0.04); for the right VN a similar correlation was established at the trend level. High-resolution ultrasound of patients with PD demonstrated atrophy of the VN and the association of VN CSA with the clinical form of the disease and the ultrasound features of the substantia nigra.

Keywords: Parkinson’s disease, vagus nerve, ultrasound, cross-sectional area.

According to pathomorphological reports, neuronal loss in the dorsal motor vagal nucleus can be as high as 50% [4]. Aggregates of α-synuclein are detected in some VN nuclei in the very early stages of the disease [5]. Importantly, subdiaphragmatic vagotomy is associated with a reduction in the subsequent risk of PD [6, 7]. A study conducted on an animal model has shown that α-synuclein derived from the brain lysate of patients with PD and recombinant α-synuclein injected into the intestinal wall are transported to CNS via the VN [8]. Abnormal α-synuclein aggregates have been detected in the glossopharyngeal and vagal...
Patients with PD

Clinical characteristics of patients with PD included in the study included 37.0 ± 16.1 points and age (mean age: 59 ± 6 years), without a medical history of diabetes mellitus, impaired glucose tolerance and neurological (including neurodegenerative) diseases.

Ultrasound examination

Transverse scans of the VN were performed using the iU 22 scanner (Philips; Netherlands) equipped with a L17-5 high-frequency linear array transducer. To measure CSA of the VN, the nerve was manually traced inside the hyperechoic epineural rim at the level of the distal portion of the common carotid artery, proximal to the bifurcation point (Fig. 1). During the scan, the pressure applied to the transducer was minimal to prevent nerve compression. The color Doppler mode was activated when necessary, so as not to confuse a small blood vessel in this hypervascularized region for VN. CSA was measured with 0.1 mm² precision. The average value derived from the sum of 3 measurements on each side was used in the subsequent statistical analysis.

Transcranial ultrasound of the substantia nigra was performed using the same scanner, an S5-1 sector array transducer and the standard technique described in [24]. Longitudinal scans were performed bilaterally using the transtemporal approach (temporal bone acoustic window). The images of the middle cerebral peduncles, which are visualized as a hypoechoic structure resembling a butterfly and surrounded by the hyperechoic basal cisterns, were captured and zoomed in 200% or 300%. If a hyperechoic signal was registered from the anatomic location of the substantia nigra (substantia nigra hyperchogenicity, SNH), that region was delineated with a cursor and CSA (cm²) was calculated automatically.

Statistical analysis

Statistical analysis was carried out in StatTech v. 2.3.0 (StatTech; Russia). For quantitative variables, normality of distribution was tested using the Shapiro–Wilks test. Normally distributed quantitative variables were described as arithmetic means (M) and standard deviations (SD). Non-normally distributed quantitative variables were described as medians (Me) and the upper and lower quartiles (Q₁; Q₃). Intergroup differences in normally distributed quantitative variables with equal variances were estimated using Student’s t-test. Intergroup differences in non-normally distributed quantitative variables were estimated in the Mann–Whitney U test. The direction and strength of correlations between two quantitative variables were assessed using Spearman’s correlation coefficient. ROC-curve analysis was applied to assess the diagnostic significance of quantitative parameters in predicting a given clinical outcome. The optimal cutoff point was calculated based on the maximum value of the Youden index. The significance threshold was assumed to be p < 0.05.

Youden index. The significance threshold was assumed to be p < 0.05.
RESULTS

The analysis revealed that CSA of the right VN was reliably larger than that of the left VN in both groups (p < 0.001; Table 2).

No significant sex-related differences between right and left VN CSAs were detected within the group of patients with PD (p = 0.16 and p = 0.19, respectively), although CSA tended to be bilaterally smaller in women (Table 2). In the control group, left VN CSA was smaller in women than in men (p = 0.03) but right VN CSA did not differ between the sexes (p = 0.08; Table 2).

The analysis also showed that left VN CSA was smaller in patients with PD than in the control group (p = 0.007). Right VN CSA did not differ significantly between the groups (p = 0.09). The right and left VN CSA did not differ between female participants (p = 0.61 and p = 0.39, respectively).

Considering the differences in the left VN CSA between the PD and the control groups, we conducted ROC analysis to determine a threshold value for the left VN CSA and assessed the model’s sensitivity and specificity (Fig. 2). The threshold value of left VN CSA (the cutoff point) corresponded to the maximum value of the Youden index and was 2.10 mm²; sensitivity and specificity of the model were 59.4% and 75.0%, respectively.

The analysis of the PD group data did not detect any associations between CSA and age, clinical duration or stage of the disease, UPDRS-III and NMSQ scores (p > 0.05). However, there was an association between the form of the disease and left VN CSA; the latter was smaller in patients with akinetic rigid PD (p = 0.043). Right VN CSA only tended to be smaller for this form of the disease (p = 0.064; Table 3).

During transcranial ultrasound, SNH was detected in 27 (84%) patients. The hyperechoic area was 0.23 (0.15; 0.26) cm² on the right side and 0.22 (0.15; 0.27) cm² on the left side. The analysis of possible associations between CSA and SNH areas on both sides demonstrated a moderate inverse correlation between left VN CSA and SNH areas on the left (R = –0.38; p = 0.03) and right (R = –0.36; p = 0.04) sides (Fig. 3).

At the trend level, a similar association was observed for the right VN CSA: R = –0.352, p = 0.05 on the right and R = –0.28, p = 0.12 on the left side.

DISCUSSION

In our study, right VN CSA was reliably larger than CSA of the left VN in both groups. This pattern was observed for both male and female participants. Similar findings are reported by another study proposing reference VN CSA values for healthy populations [25] and by almost all publications on the HR-US-based assessment of the VN in patients with PD [4, 17–20, 22]. This is consistent with the difference between the right and left VNs observed during a morphological examination [26]. The amount of nerve fibers in the right VN is ~20% higher than in the left nerve [27]. This asymmetry may result from unequal innervation of unpaired organs in the abdominal cavity [28]. The right VN innervates a part of the small bowel, the colon and the anterior gastric plexus; the left VN ends in the anterior gastric plexus and branches off to the stomach, liver and the superior duodenum.

Note: CSA — cross-sectional area; VN — vagus nerve; PD — Parkinson’s disease; * — p < 0.05, comparison with the control group.
According to our observations, VN CSA was smaller in women than in men in both groups (p < 0.001). These findings are consistent with the results of the largest study on the subject [4] in which HR-US of the VN was performed on 63 patients with PD and 56 healthy individuals. However, in another study VN CSA was larger in men than in women [19].

According to our measurements, left VN CSA was smaller in patients with PD than in the control group (p < 0.05); right VN CSA did not differ significantly between the groups although it did tend to be smaller in patients with PD. Eight identified publications on HR-US-based VN assessment in patients with PD yielded conflicting data despite the use of high-frequency high-resolution transducers (linear array transducer frequencies ranged from 12 to 19 MHz; Table 4). Significant atrophy of the right and left VNs of patients with PD was reported by 4 studies [16, 19, 20, 23]. Another 4 studies included in the analysis reported no differences between the VNs of patients with PD and healthy individuals [4, 18, 21, 22]. But although no differences in VN CSA between patients with PD and the control group were initially observed in the study [4], once the obtained data were corrected for sex, right (as opposed to left), VN CSA turned to be considerably smaller for female patients with PD (p = 0.041). In our study, left VN CSA was reliably smaller in men with PD than in healthy male controls, but no significant differences were found for right VBN CSA.

In our study, the average VN CSA was 8% smaller on the right side and 15% smaller on the left side in patients with PD than in the control group. Other studies report a reduction of 10% to 30% [16, 17, 19, 20, 23]. In order to determine the threshold value for left VN CSA, which, according to our data, was reliably smaller in the PD group, ROC analysis was carried out. Based on its results, a value below 2.10 mm² may serve as a VN atrophy indicator for patients with PD with 59% sensitivity and 75% specificity. In an earlier study conducted on 60 healthy volunteers, VN CSA was 3.0 ± 0.7 (1.7–4.3) mm² on the right and 2.3 ± 0.6 (1.1–3.5) mm² on the left side [25]. Knowing that typical VN CSA varies from 1 to 4 mm² and considering the low sensitivity of this indicator, we think that the obtained threshold value cannot be used in clinical practice for such small anatomical structures as VN. It should be noted that in all of the publications we included in the analysis, the area of the nerve was measured at different levels, which may have affected the results because there is some anatomical variability in nerve thickness in its cervical segment. Similar to our strategy, some researchers measured VN CSA at the level of the distal end of the common carotid artery [16, 21]; others took measurements at the level of the thyroid cartilage [4, 19]; some studies did not specify the level at which the measurements were taken [18]. However, the difference in the applied methodologies alone cannot explain why significant atrophy of the VN was observed in some studies and was undetected in others. The conflicting results may be explained by the fact that differences in the obtained measurements were minor and generally depend on the technical specifications of the scanner, transducer frequency and the experience of the sonographer.

We did not find any correlations between VN CSA and most of the clinical characteristics of PD. There were no reports of correlations between VN CSA and the patient’s age, Hoehn & Yahr stage, duration of the disease, UPDRS-III scores, cognitive scores, gastrointestinal and other non-motor symptoms in almost all of the analyzed publications [4, 17, 18, 20–23]. The absence of correlations may be linked to the progressive degeneration of the dorsal motor vagal nucleus at the early stages of the disease [29]. However, there are publications suggesting an association between the VN caliber and the clinical manifestations of PD. For instance, left VN CSA is reported to correlate with the severity of PD symptoms on the UPDRS-III scale (r = 0.58; p = 0.007), in contrast with right VN CSA (p = 0.53) [19]. Besides, right VN CSA is correlated with bradykinesia assessed on the UPDRS-III scale (r = 0.53; p = 0.003) [18]. The authors of the cited studies hypothesize that bradykinesia-dominant PD subtypes seem to be associated with more advanced Lewy body pathology. Our findings corroborate this conclusion. In our study, the nerve caliber was associated with the form of the disease: left VN CSA was smaller in patients with akinetic rigid PD (p = 0.05) whereas a similar pattern for right VN CSA was observed at the trend level (p = 0.06).

</tbody>
</table>

*Note: * — indicates statistically significant differences (p < 0.05).
While conducting literature analysis, we found a single report of a significant inverse correlation between right/left VN CSA and the severity of autonomic dysfunction in PD measured on the NMSQ scale ($r = -0.46; p = 0.003$) [19]. Besides, right (but not left) VN CSA was directly correlated with parasympathetic heart-rate variability ($r = 0.58; p = 0.001$) whereas left VN CSA was correlated with the severity of PD symptoms on the UPDRS-III scale ($r = 0.58; p = 0.007$). This inconsistency between our findings and the results of other studies might be explained by the applied study selection criteria: patients with comorbidities that could be associated with VN neuropathy were excluded.

In the course of the study, we investigated possible associations between VN CSA and SNH in the middle cerebral peduncles assessed by transcranial ultrasound. The analysis revealed a moderate inverse correlation between the left VN CSA and SNH area on both sides ($p < 0.04$). A similar correlation for the right VN was observed at the trend level. These findings seem to reflect the neurodegenerative process in the VN and dopaminergic neurons of the substantia nigra in patients with PD. Previously, we had demonstrated that SNH area (similar to VN CSA investigated in this study) did not correlate with the duration or severity of the disease. This marker stability suggests that changes can occur at the very early stages of the disease [23, 30].

**CONCLUSIONS**

HR-US of patients with PD has revealed atrophy of the VN and associations of VN CSA with the clinical form of PD and the changed echogenicity of the substantia nigra. However, the low sensitivity of the described VN assessment method prevents using HR-US as a diagnostic modality in wide clinical practice. Thus, VN CSA is not a reliable marker of VN damage.

Studying the effects of regulatory peptides on the stress-induced shifts in the bodily processes is of great fundamental and applied significance. Currently, a wide range of peptide neurotropic drugs, affecting the stress response development, are used in medicine, and new promising molecules are being studied. The study was aimed to assess the effects of the adenocorticotropic hormone (ACTH) synthetic analog, ACTH(6-9)-Pro-Gly-Pro, administered at a dose of 5, 50 and 500 μg/kg, on the free-radical oxidation processes in Wistar rats, subjected to chronic restraint stress (CRS) during two weeks. Serum levels of 8-oxo-2’-deoxyguanosine (8-OHdG) and superoxide dismutase 3 (SOD3) were assessed by enzyme immunoassay, and the levels of thiobarbituric acid reactive substances (TBARS) were assessed by fluorimetric method. CRS lead to the significant increase in the 8-OHdG levels by 18.4% (p = 0.01) and the decrease in the SOD3 levels by 14.3% (p = 0.01), however, it had no effect on the levels of TBARS. ACTH(6-9)-Pro-Gly-Pro, administered at a dose of 5 and 50 μg/kg, significantly decreased the levels of 8-OHdG by 19.8% (p = 0.03) and 30% (p = 0.001), respectively. Thus, it was found that CRS resulted in oxidative stress in animals. ACTH(6-9)-Pro-Gly-Pro administration at a dose of 5 and 50 μg/kg inhibits the stress-induced free-radical oxidation processes.

Keywords: regulatory peptides, His-Phe-Arg-Trp-Pro-Gly-Pro, ACTH(6-9)-Pro-Gly-Pro, free-radical oxidation, oxidative stress, chronic restraint stress

Author contribution: Vorvul AO — performing experiments, quantification of oxidative stress markers, data acquisition and statistical processing, manuscript writing; Bobyntsev II — study concept and design, manuscript writing; Medvedeva OA — study concept and design; Azarova YuE — quantification of oxidative stress markers; Belykh AE — manuscript writing; Andreeva LA — study concept and design, peptide synthesis.

Compliance with ethical standards: the study was approved by the Ethics Committee of the Kursk State Medical University (protocol № 3 dated November 16, 2020), all the experiments were in line with the ARRIVE guidelines and were performed in accordance with the Directive 2010/63/EU of the European Parliament and of the Council on the protection of animals used for scientific purposes.

Original research | Pathophysiology

Activation of free-radical oxidation is one of the main mechanisms, underlying cell damage, resulting from the organism’s exposure to stressor [1, 2], which determines the relevance of searching for effective approaches to cytoprotection under the condition of stress. The use of peptide molecules could be one of the promising directions for solving the mentioned above problems [3, 4]. No toxicity and allergenic capacity along with the broad spectrum of physiological and pharmacological activity is the advantage of using the drug products based on regulatory peptides [5].
These molecules include regulatory peptides, belonging to the group of N-terminal analogs of adrenocorticotropic hormone (ACTH). It is well known that Semax, containing the ACTH(4-7)-Pro-Gly-Pro synthetic peptide as an active substance, corrects histoarchitectonic and free-radical oxidation processes in the liver, as well as serum transaminases levels in the stressed rats [6]. Furthermore, Semax exhibits neuroprotective effects due to increased expression of brain-derived neurotrophic factor (BDNF) in the conditions of brain ischemia [7].

The His-Phe-Arg-Trp-Pro-Gly-Pro peptide (ACTH(6-9)-Pro-Gly-Pro) is structurally and functionally related to Semax. The His-Phe-Arg-Trp-Pro sequence, matching the ACTH(6-9) region, is an active center of ACTH, which interacts with melanocortin receptors (MCR) of all types, except MC2R [8]. However, attachment of the Pro-Gly-Pro tripeptide to the C-terminus of this molecule increases the molecule resistance to carboxypeptidases against the background of preserved neurotropic effects. Like Semax, ACTH(6-9)-Pro-Gly-Pro exhibits a broad range of neurotropic effects, including in the stressor load models, and is capable of exhibiting the more prominent activity when administered at comparable doses [9].

Therefore, the study was aimed to assess the effects of the ACTH(6-9)-Pro-Gly-Pro peptide on the free-radical oxidation processes in rats subjected to chronic restraint stress (CRS).

METHODS

Animals

The experiment involved 55 male Wistar rats weighing 280–300 g. The temperature of 22 ± 2 °C, humidity of 60 ± 5%, and the 12-hour light/dark cycle (light on from 8:00 to 20:00) were maintained in the room where the animals were kept. The temperature of 22 ± 2 °C, humidity of 60 ± 5%, and the 12-hour light/dark cycle (light on from 8:00 to 20:00) were maintained in the room where the animals were kept. The animals were provided ad libitum access to food and water. The animals were divided into five groups, 11 rats per group: 1 — intact animals (administration of normal saline (NS) with no stress applied); 2 — control group (CRS + NS), 3 — CRS + ACTH(6-9)-Pro-Gly-Pro 5 μg/kg, 4 — CRS + ACTH(6-9)-Pro-Gly-Pro 50 μg/kg, 5 — CRS + ACTH(6-9)-Pro-Gly-Pro 500 μg/kg.

Chronic restraint stress

The CRS model was modeled by placing the rats in the tight transparent plastic boxes with ventilation holes, the size of which was adjusted individually for each animal. The animals were subjected to stress for 2 h (from 11:00 to 13:00) during 14 days (Fig. 1) [10].

Peptide

The N-terminal analog of ACTH, ACTH(6-9)-Pro-Gly-Pro (His-Phe-Arg-Trp-Pro-Gly-Pro), synthesized in the Institute of Molecular Genetics of the National Research Centre "Kurchatov Institute" (RAS), was used during the study, which was dissolved in NS and administered intraperitoneally at a dose of 5, 50 and 500 μg/kg daily 12–15 min before stress exposure in a volume of 1 mL per kg of body weight. Intact animals and controls received equivalent amounts of NS on a daily basis. The peptide doses and the procedure for administration, used during the experiment, were selected in accordance with the available literature data on their efficacy [9, 11].

Blood serum collection

The animals were euthanized 24 h after the final stress exposure by blood withdrawal from the right ventricle of the heart after performing parasternal bilateral thoracotomy under ether anesthesia using the S-Monovette vacuum system with procoagulant (SARSTEDT; Germany). A total of 7.0–7.5 mL of blood was collected; the vacuum system needle position was assessed visually. The blood samples collected were centrifuged at 1500 g for 15 min. The serum obtained was distributed in 200 μL aliquots in the clean individual microtubes, frozen at –20 °C, and then stored at –80 °C for further study. Aliquots were thawed at room temperature for 4 h prior to analysis.

Assessing the intensity of free radical processes and the stress response intensity

The nucleic acid metabolite 8-oxo-2′-deoxyguanosine (8-OHdG) was selected as a marker of oxidative damage to cellular DNA, it was assessed by enzyme immunoassay (ELISA) using the DNA/RNA Oxidative Damage (High Sensitivity) ELISA Kit (589320, Cayman Chemical; USA). Moreover, the concentration of extracellular superoxide dismutase (SOD3) was defined by ELIZA using the ELISA Kit For Superoxide Dismutase 3, Extracellular (SEA117Ra, Cloud-Clone Corp.; USA); thiobarbituric acid reactive substances (TBARS) were assessed by fluorimetric method using the TBARS (TCA Method) Assay Kit (700870, Cayman Chemical; USA).

To evaluate the stress response intensity, corticosterone serum levels were defined by enzyme immunoassay using the Corticosterone ELISA kit (AD1-900-097, Enzo Life Sciences; USA).

All the assays were performed in accordance with the manufacturers’ procedures. Absorbance and fluorescence were registered and analyzed using the Varioskan Flash advanced spectral scanning multimode reader (Thermo Fisher Scientific; USA) and the SkanIt software (Thermo Fisher Scientific; USA).

Statistical analysis

Statistical processing of the data obtained was performed using v.4.1.0 of R language [12] in the RStudio Desktop v. 1.4.1717 integrated development environment (RStudio, PBC; USA; https://www.rstudio.com). The Shapiro–Wilk test was used for the normality hypothesis test, and equality of variances was tested using the Levene's test. In case of the hypothesis confirmation, two groups were compared using the Welch’s t-test, and four groups were compared using one-way ANOVA with post hoc Newman–Keuls test. In case of the hypothesis rejection, the Mann–Whitney U test was used for two groups, and the Kruskal–Wallis test with post hoc Dunn’s test were used for four groups. The Benjamini–Hochberg procedure was applied to reduce the false discovery rate. The differences were considered significant when $p < 0.05$.

RESULTS

The study found that CRS resulted in oxidative stress (Fig. 2). Thus, a significant increase in the levels of 8-OHdG by 18.4% ($p = 0.01$) along with the significant decrease in the levels of SOD3 by 14.3% ($p = 0.01$) against the background of CRS were observed. However, the concentration of TBARS did not change ($p = 0.43$).

At the same time, it has been shown that ACTH(6-9)-Pro-Gly-Pro corrects the CRS-induced oxidative stress. The significant differences in the serum 8-OHdG levels ($p = 0.0004$) between the controls, subjected to stress, and the animals, receiving the peptide, have been revealed. However, no significant differences in the levels of SOD3 ($p = 0.2$) have been found.
Fig. 1. Study design

The post hoc analysis has found that the serum 8-OHdG levels significantly decreased by 19.8% (p = 0.03) and 30% (p = 0.001), respectively, after the ACTH(6-9)-Pro-Gly-Pro administration at a dose of 5 and 50 μg/kg. However, peptide administration at a maximum dose of 500 μg/kg had no effect on the 8-OHdG levels (p = 0.72).

Based on the data obtained, it was also found that the significant increase in the levels of corticosterone by 27% (p = 0.009) was observed in the CRS model. The use of ACTH(6-9)-Pro-Gly-Pro resulted in significantly altered levels of the hormone (p = 0.003). The post hoc analysis showed that ACTH(6-9)-Pro-Gly-Pro administration at a dose of 5, 50, 500 μg/kg resulted in the significant decrease in the levels of corticosterone by 34.9% (p = 0.004), 16.4% (p = 0.04), and 28.6% (p = 0.01), respectively.

DISCUSSION

The effects of the ACTH(6-9)-Pro-Gly-Pro peptide on the free-radical oxidation processes in rats against the background of CRS were assessed during the study. The free-radical oxidation markers, which were used in the study, were selected based on their diagnostic and pathophysiology value. Thus, 8-OHdG is a reliable biomarker of the generalized and cellular oxidative stress, and an important indicator of oxidative brain damage in acute ischemic stroke, atherosclerosis, cardiovascular diseases, neurodegenerative disorders, such as Alzheimer’s disease and Parkinson’s disease, as well as in mental disorders, such as schizophrenia, etc. [13]. The other selected marker of oxidative stress is malondialdehyde (MDA), resulting from peroxidation of polyunsaturated fatty acids, which is used as an indicator of the reactive oxygen species-mediated damage to cell membranes. The levels of MDA are measured by TBARS assessment [14]. SOD is a first-line antioxidant, which initiates activation of protection against the reactive oxygen species [15]. Three isoforms of SOD have been reported, however, extracellular SOD3 is a predominant antioxidant enzyme of blood serum, and the role of SOD3 is not confined to free-radical scavenging, but also involves the impact on the immune response and cell signaling [16]. Consequently, ELISA was used as a reliable and specific research method, allowing one to identify this exact isoform of the enzyme, in order to evaluate the SOD3 level changes in the conditions of CRS and peptide administration.

The study found that CRS resulted in significantly increased concentrations of the DNA/RNA free-radical oxidation products in blood serum of experimental animals. These results were obtained in the similar C57BL/6J murine model of chronic stress [17]. Furthermore, CRS resulted in the decreased SOD3 levels. It should be noted that free-radical oxidation activation and the decrease in the SOD3 concentration occurred against the background of the elevated corticosterone blood levels. It is known that elevated corticosterone levels are accompanied by a decline in the antioxidant enzyme system activity [18]. Thus, the chronic stress model, which was used in the study, induced activation of the free radical oxidation processes.

It was found that CRS caused no significant changes in the levels of TBARS. However, there are contradictory data in the literature regarding the serum levels of this marker under prolonged stressor exposure. Thus, in a number of studies, chronic stress resulted in significantly increased serum concentrations of TBARS [19, 20]. However, the changes observed occurred against the background of chronic unpredictable stress, characterized by exposure to stressors of various intensity, while we used a model involving exposure to monotonic stress. At the same time, there are some papers, reporting no significant changes in the serum levels of TBARS in the experimental conditions similar to ours, regardless of the significantly increased MDA concentration in the organs and tissues [18, 21]. It is also important to mention that, despite their speed and simplicity, fluorometric and spectrophotometric
methods for TBARS assessment are not always reliable in heterogeneous systems due to the potential of aldehydes other than MDA to produce derivatives, absorbing light in the same wavelength range [14]. At the same time, the lack of significant changes in the serum concentrations of TBARS may be also due to the increase in the activity of the antioxidant mechanisms, unexplored during our study, by the end of the experiment. Therefore, clarifying the mechanisms, underlying alterations in the free-radical oxidation processes, identified during our study, requires further identification of a number of additional markers in blood serum.

ACTH(6-9)-Pro-Gly-Pro, administered at a dose of 5 and 50 μg/kg, reduced the intensity of free-radical oxidation processes, as reflected in the significantly decreased 8-OHdG levels. In this regard, it should be pointed out that ACTH(4-7)-Pro-Gly-Pro (Semax), which is similar to ACTH(6-9)-Pro-Gly-Pro based on its structural and functional properties, administered at comparable doses, has a cytoprotective effect on the neurons of the brain in the conditions of ischemia, in particular, due to the elevated neuronal expression of BDNF [6, 22, 23].

Moreover, it is well known that hypothalamic-pituitary-adrenal axis, involved in both production and release of cortisol, is capable of increasing oxidative stress due to modulation of the reactive oxygen species production together with mitochondrial calcium homeostasis. However, cortisol levels correlate positively with plasma 8-OHdG concentrations [27]. Given the neurotropic activity, exhibited by ACTH(6-9)-Pro-Gly-Pro [9], it can be assumed that the anti-stress effects of the substance may be also associated with modulation of stress response in the central nervous system, as evidenced by simultaneous decrease in the levels of cortisol and 8-OHdG, observed during our study.

The differences in the effects of ACTH(6-9)-Pro-Gly-Pro depending on the dose, in particular, the lack of activity when using the maximum dose (500 μg/kg), is typical for regulatory peptides [5, 9]. Thus, as it has been shown for melanocortins, the signal is transduced from MC3R via interaction with adenylyl cyclase and activation of the cAMP signaling pathway [28]. However, the signal transduction pathways may depend on the ligand concentration and the transduction may involve other secondary messenger systems, which may affect the effects direction and severity. For example, the signal from MC3R may be transmitted via phosphoinositol pathway [29], and the signal transduction from MC5R may involve Jak/STAT [30].

CONCLUSIONS

The study showed that in animals, chronic (14-day) restraint stress resulted in activation of the free-radical oxidation processes. Administration of ACTH(6-9)-Pro-Gly-Pro at a dose of 5 μg/kg reduced the intensity of stress response and inhibited the stress-induced free-radical oxidation processes.
Our findings and the data of other studies, focused on the effects of the N-terminal ACTH analogs, indicate the need for further investigation of the mechanisms underlying the effects of those on the stress-induced free-radical oxidation with the use of more complex evaluation of the wider range of prooxidant and antioxidant system markers.

The modern personalized approach to phage therapy is based on the detailed assessment of the interaction between phages and bacterial cells. Bacterial carbohydrates exposed on the cell surface, O-antigens and capsular polysaccharides, are one of the most important specificity determinants in the phage–cell interaction. Capsular polysaccharides of K. pneumoniae, being the virulence factors [1], are highly diverse in their structure. Currently, bioinformatics databases indicate the existence of at least 134 genetic variants [2]. To meet the challenges of clinical practice it is necessary to create the collection of phages with
the defined specificity, inter alia based on their capacity of adsorption through recognition of capsular polysaccharides with certain structure. The study was aimed to isolate the virulent phage, which specifically infected the previously described *K. pneumoniae* strains with the KL108 capsular polysaccharide, as well as to fully explore the biological and genetic features of the phage. Standard phage biology methods, electron microscopy, and bioinformatics, including the advanced methods for protein structure prediction (AlphaFold software) were used in order to provide the comprehensive description of the phage.

**METHODS**

The P224 (1732) and P225 (1333) clinical strains of *K. pneumoniae* with the K108 type capsular polysaccharide were obtained from the collection of the Institute of Epidemiology (Moscow, Russia). The wastewater samples, collected from the wastewater treatment facilities in Moscow, were used for bacteriophage isolation. Dry components of the bacterial culture medium (trypton, 10 g/L, yeast extract, 5 g/L, NaCl, 5 g/L) were added to the wastewater samples previously clarified by centrifugation, then the media were inoculated with the bacterial cells culture being in the phase of exponential growth. Cultivation was carried out at 37 °C for 16 h. The bacterial culture was subsequently inactivated with chloroform, and the samples were clarified by centrifugation. Phages were detected by titration using the double-layer agar plate method. The isolated phage was titrated twice in a row in order to obtain single phage plaques. Preparative bacteriophage growth was performed in 1 L of the P224 strain culture at 37 °C. Bacteriophage was precipitated with polyethylene glycol and purified by caesium chloride density gradient ultracentrifugation [3].

Genomic DNA of the phage was extracted from the purified phage preparation by incubation with the solution, containing 100 mM Tris-HCl (pH 7.5), 25 mM EDTA, 1.5 M NaCl, 2% (w/v) CTAB buffer, 0.3% (v/v) β- mercaptoethanol, and 50 mg/mL of proteinase K, at 50 °C for 30 min, with subsequent chloroform precipitation of double-stranded DNA 43,755 bp in length with the direct terminal repeats 244 bp in size. The GC-content is 53.6%, somewhat lower than the value of 57.5%, characteristic of the large subunit, DNA polymerase, and RNA polymerase. The sequences were aligned with the MAFFT program [16] and concatenated with the Geneious Prime software [10]. The intergenomic comparison diagram was created with the Easyfig application [17] using the TBLASTX tool [7] to find the homologous regions within genomes.

The models of the gene 8 product tertiary structure and the tailspike protein quaternary structure for the *Klebsiella* bacteriophage KPP108.1 were constructed with the AlphaFold-Multimer application [18, 19]. The tailspike protein structure of the *Enterobacteria* phage –92 was downloaded from the PDB database [20]. Electrostatic surface charge of the tailspike protein was calculated using the APBS program [21]. The UCSF Chimera program was used for structure alignment and visualization [22].

**RESULTS**

The KPP108.1 bacteriophage forms clear plaques, 5 mm in diameter, surrounded by the translucent halos, in the bacterial cultures grown on the agar plates (Fig. 1). The presence of a halo typically indicate the presence of phage-derived depolymerase, which has been confirmed by further research. The one-step growth curve showed a latent period of 15 min and burst size of 46 phage particles per one infected cell.

*Klebsiella* bacteriophage KPP108.1 has a genome, typical for the *Autographiviridae* phages, which consists of double-stranded DNA 43,755 bp in length with the direct terminal repeats 244 bp in size. The GC-content is 53.6%, somewhat lower than the value of 57.5%, characteristic of the sequenced *K. pneumoniae* strain HS11286 (GenBank Accession
The search for coding sequences revealed a total of 56 protein-coding genes and no tRNA-encoding genes in the genome. The search for homologous and similar sequences using the BLAST algorithm and the HMM-HMM comparison in public databases and web servers made it possible to predict the functions of 29 proteins, encoded in the genome. It was not possible to identify the functions of 27 proteins. No genes, encoding integrases or other proteins specific to temperate phages, were found in the genome.

Comparison of the average nucleotide identity (ANI), involving all 14,923 genes of tailed bacteriophages, deposited in the NCBI Genome database, revealed a group of Klebsiella bacteriophages of the genus Drulisvirus, being the most close to phage KPPK108.1 based on this parameter. The ANI values of phage KPPK108.1 and a typical phage of the genus Drulisvirus, Klebsiella phage KP34, are 73.0%. Phylogenetic analysis, performed with the use of the concatenated amino acid sequences of the major capsid protein, large terminase subunit, DNA polymerase, and RNA polymerase, shows that Drulisvirus bacteriophages and KPPK108.1 phage form a monophyletic group. The genetic makeup and genomic organization of the phage KPPK108.1 are generally similar to those of other Autographiviridae phages, and are almost identical to those of other members of the genus Drulisvirus. An interesting feature of the gene 8 product was found. Protein structural modeling revealed unusual L-shape of the protein with a tubular C-terminal region. This region was characterized by the number of positively charged amino acid residues above the average. Electrostatic field simulation showed that the C-terminal region of the gene 8 product had a significant negative surface charge (up to –5).

Bioinformatic analysis of the KPPK108.1 phage genome revealed genes, encoding the head-tail connector and tailspike proteins. Modeling and analysis of the tailspike protein structure was performed. The search for similar structures revealed a high degree of similarity between the tailspike of the phage KPPK108.1 and the tailspike of the Enterobacteria phage –92 (PDB entry 6E0V) exhibiting colanidase activity confirmed by experimental data.

The genome-wide similarity score of the phages KPPK108.1 and KP34 exceeding 70% of the genus boundary, together with the results of the phylogenetic analysis performed based on the concatenated sequences of conservative genes, show that the Klebsiella phage KPPK108.1 belongs to the genus Drulisvirus, subfamily Slopekvirinae, family Autographiviridae. Intergenomic comparisons support this finding. Minor differences in genome organization can be explained by the recombination events that took place during the Klebsiella bacteriophages’ evolution, as confirmed by the presence of NHN endonuclease genes in the genomes of KPPK108.1 and other related bacteriophages. The genome structure of the KPPK108.1 phage is typical for bacteriophages of the Autographivirinae family and is characterized by the presence of the early gene region.

**DISCUSSION**

The genome-wide similarity score of the phages KPPK108.1 and KP34 exceeding 70% of the genus boundary, together with the results of the phylogenetic analysis performed based on the concatenated sequences of conservative genes, show that the Klebsiella phage KPPK108.1 belongs to the genus Drulisvirus, subfamily Slopekvirinae, family Autographiviridae. Intergenomic comparisons support this finding. Minor differences in genome organization can be explained by the recombination events that took place during the Klebsiella bacteriophages’ evolution, as confirmed by the presence of NHN endonuclease genes in the genomes of KPPK108.1 and other related bacteriophages. The genome structure of the KPPK108.1 phage is typical for bacteriophages of the Autographivirinae family and is characterized by the presence of the early gene region.

Regardless of the fact that...
Fig. 3. Average nucleotide identity (ANI) distance matrix of the Klebsiella phage KPPK108.1 generated with the VIRIDIC web-based tool using the genomes of various Autographiviridae family members.

The function of this protein has not been defined by searching for homologues using BLAST, or searching for similar proteins by HMM-HMM comparison, the surface charge distribution makes it possible to assume that this protein mimics nucleic acid, like Ocr proteins, which are also located within the early gene regions in the genomes of other Autographiviridae, and are capable of DNA mimicking [25, 26]. It has been shown that Ocr protein effectively inhibits the BREX restriction modification system, facilitating phage infection [27].

Bioinformatic analysis of the KPPK108.1 phage genome makes it possible to predict the organizational structure of the adsorption apparatus comprised of the head-tail connector and the tailspike protein, possessing enzymatic properties. The tailspike protein seems to be the receptor-binding protein (RBP), which determines host specificity and the host spectrum of the phage [28]. The tailspike protein structure analysis indicates the presence of depolymerizing activity against the polysaccharide, presumed to be related to the E. coli colanic acid. Colanic acid, the extracellular polysaccharide, consisting of several types of carbohydrate residues (such as L-fucose, D-glucose, D-galactose, and D-glucuronic acid), which is released into the extracellular environment by bacteria of the Enterobacteriaceae family, is the colanidase substrate [29]. Colanidases have been relatively recently discovered in phage RBPs [30]. Colanidases are present in a number of virulent bacteriophages of the evolutionarily distant groups, such as podoviruses and myoviruses [23, 30], some of which have proven to be effective when used in phage cocktails for phage therapy [30]. It is essential to define the structure of the type K108 K. pneumoniae capsular polysaccharide to clarify the question of the similarity of this polymer to colanic acid.

CONCLUSIONS

Klebsiella bacteriophage KPPK108.1 is a virulent bacteriophage of the genus Drulisvirus, family Autographiviridae. Thorough
bioinformatic analysis has revealed the lytic nature of the phage infection cycle. The analysis makes it possible to predict the structure of the phage adsorption apparatus comprised of the head-tail connector and the tailspike protein, exhibiting colanidase activity. The predicted characteristics of KPPK108.1 bacteriophage indicate the feasibility of using KPPK108.1 in phage cocktails for phage therapy. As far as we know, KPPK108.1 is the first fully described phage specific for capsular type KL108.

Боль в спине (БС), ассоциированная с дегенеративной болезнью диска (ДБД), — тяжелое социальное и экономическое бремя вследствие ранней инвалидизации и возникновения показаний к оперативному вмешательству уже в молодом возрасте. Патофизиологические основы преждевременной дегенерации межпозвонкового диска (МПД) находятся на стадии активного изучения. Целью исследования было определить профиль воспалительных цитокинов при ДБД и их связь со структурными нарушениями позвоночника. У пациентов моложе 25 лет, поступивших в клинику с БС или острой болью в спине, получены образцы из межпозвонковых дисков (МПД) и фрагменты межпозвонковых пластин и Modic (модич) изменения. В лейкоцитах крови и тканях МПД участники исследования установили высокий уровень экспрессии цитокинов TNF-α и IL-17, IL-6, что было подтверждено экскрецией в межпозвонковом диске (МПД) и фрагментах межпозвонковых пластин с сопротивлением к реакции с регионарным нейтропеническим синдромом. Выданы рекомендации по адекватной и комплексной терапии, включающей контроль над воспалительными процессами и применение препаратов противовоспалительной и репаративной терапии, что значительно улучшает качество жизни пациентов с дегенеративной болезнью диска в молодом возрасте.

Back pain (BP) is one of the main causes of the patients’ disability in the developed world, resulting in permanent disability. BP is found in all age groups. Thus, according to a Polish study, BP recurrence within 34 years was observed in 85% of males and 86% of females with the BP onset at the age of 14 [1]. Degenerative disc disease (DDD), resulting from degradation and inflammation of the intervertebral disc (IVD) tissues, is one of the BP variants, associated with unfavourable outcomes [2]. DDD is a chronic condition with a trend towards progression. Despite the fact that there are still no explicit criteria for distinguishing between the “natural” physiological disc ageing and the pathological degeneration, also found in younger subjects [3], the term “DDD” is used by both clinicians and pathologists to define the disc extracellular matrix disruption with impaired homeostasis and the inflammatory process induction in the IVD space [3]. The DDD clinical manifestations are well documented: those are BP of mechanical origin associated with axial load (getting worse with physical activity, moving heavy objects, flexion, and improving at rest) and/or with spine stiffness, radiculopathy, and less often with myelopathy.

DDD is one of the causes of chronic segmental instability and early disability in the working age patients. Studies have shown that the IVD degeneration is a multifaced process, involving apoptosis, inflammation, ageing, and biomechanical dysfunction [4]. Recently, considerable attention has been paid to studying the effects of inflammatory cytokines on the DDD development, as well as to the imbalance between the pro-inflammatory and anti-inflammatory cytokines [5].

It is shown, that inflammatory pattern triggers the catabolic processes in the cartilage matrix of the compromised functional spinal unit, together with further degeneration of extracellular matrix and dehydration of nucleus pulposus (NP) and annulus fibrosus (AF) [5]. The term “DDD” is used by both clinicians and AF microcracks cause the rupture of the NP content into the IVD tissue and outwards with the formation of protrusion, extrusion, and sequestration. The role of TNFα, IL1β, overexpression of IL6, and CD16 monocytosis in the development and progression of degenerative changes is being discussed in literature. It is important to mention that the cytokine expression may be correlated with the IVD degeneration severity. The role of IL6 in the disc degeneration and herniation was studied by many researchers [7]. The hypothesis about the IL6 involvement in the human IVD degeneration was confirmed by the fact that the abundance of the catabolic gene transcript increased, and the expression of genes encoding proteoglycans was suppressed with the increase in the IL6 expression [8]. Studying the role of IL17 in the DDD-associated inflammatory cascade showed that the exposure of human NP cells to IL17 and TNFα contributed to the increased release of IL6 in vitro and the increased expression of intercellular adhesion molecules (ICAM-1) on the surface of cells in NP and AF [9]. The association between pain intensity, IVD herniation, and inflammatory response was defined. It was suggested to treat the listed above biomarkers as the potential markers of the disease onset, severity, and progression.

The possibility of using the analysis of serum inflammatory biomarkers for identification of degeneration and inflammation of the IVD tissues in patients with DDD was demonstrated [7, 10]. Molecular patterns of degeneration and inflammation in the disc tissues were assessed in order to develop the approaches to the reparative therapy of DDD [3]. IL1β, TNFα, and VEGF were verified by immunohistochemistry in individuals of various ages having no symptoms of BP [11]; the expression of these markers in the disc tissues showed almost no differences between the groups of young and elderly individuals having no symptoms of the disease. Accordingly, measuring the cytokine levels in the damaged disc is an important challenge in terms of searching for the pathogenetically substantiated anti-inflammatory and reparative therapy. Recently, the role of the vascular endothelial growth factor (VEGF, VFA) in the disc tissue vascularization (the disc is normally avascular) at all stages of the IVD degeneration was shown. The VEGF activity is realized via regulation of the soluble vascular endothelial growth factor receptor 1 expression [12].

When studying the pattern of the hemia resorption in patients with DDD (confirmed by MRI), Japanese researchers assessed the interaction sequence TNFα–VEGF–MMP (matrix metalloproteinases MMP-3 and MMP-7 involved in degradation of the extracellular matrix proteins, aggrecan and collagen) and found that the expression of mRNA and VEGF protein increased in the situation of the contact between macrophages and human disc tissues in vitro, and positively correlated with the TNFα expression levels [13]. Thus, it was shown that neovascularization promoted the reverse development of intervertebral hernias. The process of the capillary ingrowth into the IVD tissue was confirmed by magnetic resonance imaging (MRI) with the use of gadolinium-based contrast agents, and could serve as an additional determinant of the extrusion resorption [14].

The relationship between the markers of aseptic inflammation and IVD reparation in the disk tissues, and the abundance of those in peripheral blood of young patients with advanced grade DDD have not been fully defined. Various data are available on the preponderant role in altering the IVD immune homeostasis, played by one or another cytokine. Studying the cytokine profile (together with the features of the functional spinal unit lesion) would make it possible to define the immune phenotypes of patients in order to develop the biological targets for therapy and prognosis of the disease. The study was aimed to define the profiles of the key biomarkers of inflammatory damage (TNFα, IL6, IL17, IL1β) and angiogenesis (isoforms of the vascular endothelial growth factor A, VEGF121, VEGF165, and VEGF189) in the cartilage tissue of IVDs and white blood cells of young patients with DDD, who underwent discectomy, compared to controls.

METHODS

The study was carried out at the Department of Neurosurgery, Progrov City Clinical Hospital № 1, and A.I. Nesterov Department of Faculty Therapy, Progrov Russian National Research Medical University, in 2019–2021. A total of 87 young (aged 18–44 in accordance with the WHO classification, 2012) adults were enrolled (40 males and 48 females). Index group inclusion criteria: young patients (median age 37.01 years [35.54–38.49]) having BP associated with DDD, confirmed by instrumental evaluation (MRI) (Table). Exclusion criteria: history of spinal injury or spinal injury at the time of the study, tumors and infections affecting the spine and other organs, inflammatory spondyloarthropathy, surgical interventions in the previous 30 days. All individuals in the index group underwent surgery (microdiscectomy) due to the spinal disc herniation at the corresponding level in the lumbar spine. Pain intensity was measured in millimeters using the Visual Analogue Scale (VAS). The functional limitations in the lumbar spine were assessed based on the Backache Index (BAI) [15]. The control group was represented by healthy volunteers with no BP (20 individuals), comparable in gender and age. All patients and controls underwent MRI of the lumbar spine prior to surgery. IVD degeneration was assessed based on the reduced IVD

signal intensity, disc space narrowing, structural changes in the disk, and blurring between the nucleus pulposus (NP) and the annulus fibrosum (AF). IVD degeneration was graded in accordance with the C.W. Pfirrmann grading system (2001) (grades 1–5). Grades 3, 4, 5 were treated as irreversible damage to the disc, and grades 4, 5 were interpreted as severe DDD.

The fragments of degenerative IVDs were obtained during discectomy. Microparticles of IVD smaller than 1 mm<sup>3</sup> were immediately immersed in the IntactRNA stabilization solution (non-toxic aqueous fixative solution for rapid stabilization of cellular RNA in tissues and cell cultures, preserving the cell integrity), and the disc tissue samples were assigned a barcode, identical to the barcode of the patient’s blood samples. The same molecular markers were identified in blood and cartilage tissue samples, selected in accordance with the recent data based on the review articles and technical accessibility of the laboratory diagnosis (DNA-Technology; Russia). The abundance of mRNAs of the studied genes in blood cells (white blood cells) and IVD tissue was defined by the reverse transcription-quantitative polymerase chain reaction method with the use of the reagent kits (DNA-Technology; Russia). Amplification was performed in the DTprime 4 PCR system (DNA-Technology; Russia).

Obtaining IVD tissue samples (1 mm<sup>3</sup>): RNA was extracted after cutting the cartilage with surgical blade (sterile disposable surgical scalpel, manufactured by Huaiyin Medikal Instruments Co., Ltd., China). After cutting, the fragment sized 1 mm was obtained, which was further grinded by rubbing the cornus of the microcentrifuge tube against the Petri dish bottom in order to obtain fine particles and molds. Then 320 μL of the lysing solution from the Proba-NK kit (DNA-Technology; Russia) were added to the dish. The contents of the dish together with the crushed sample were transferred to the Axygen microcentrifuge tubes (Axygen, Inc.; USA), and then mixed using the Micro-Spin FV-2400 centrifuge/vortex (Biosan; Latvia) for 5 s, and sedimented. Subsequently, this was left to lyse for 1 h. After that RNA was isolated using the Proba-NK kit (DNA-Technology; Russia) in accordance with the manufacturer’s guidelines. The extracted RNA in the amount of 16.5 μL was immediately used for reverse transcription, which was performed at a temperature of 40 °C for 30 min, with subsequent inactivation of reverse transcriptase at 95 °C for 5 min. The resulting cDNA solution was either immediately used for quantitative PCR, or stored at −20 °C. The volume of 35 μL was used for amplification with the real-time registration of the results in accordance with the following program: 50 cycles 94 °C — 10 s, 64 °C — 20 s, 72 °C — 10 s. Fluorescence was measured during each cycle at a temperature of 64 °C.

The 4 ml blood samples were collected into the disposable Vacutainer EDTA tubes (Becton Dickinson; USA) 24 hours before surgery with subsequent blood processing in order to extract white blood cells. To obtain the buffy coat, the Proba-Ficoll kit for extraction of lymphocytes from the whole blood was used.
RNA was isolated using the Proba-NK kit (DNA-Technology; Russia) in accordance with the manufacturer’s guidelines. RNA extracted in the amount of 16.5 μL was immediately used for reverse transcription, which was performed at a temperature of 40 °C for 30 min, with subsequent inactivation of reverse transcriptase at 95 °C for 5 min. The resulting cDNA solution was either immediately used for quantitative PCR, or stored at -20 °C. The volume of 35 μL was used for amplification with the real-time registration of the results in accordance with the following program: 50 cycles 94 °C — 10 s, 64 °C — 20 s, 72 °C — 10 s. Fluorescence was measured during each cycle at a temperature of 64 °C.

The studied genes included TNFα, IL6, IL17, IL1β, and isoforms of vascular endothelial growth factor A (VEGF121, VEGF165, VEGF189). Normalization genes were represented by β2-microglobulin (B2m), and β-glucuronidase (GUSB). Normalization values for each gene mRNA were calculated by the ΔΔCt method [16]. The expression levels of the gene mRNAs were expressed in arbitrary units in relation to normalization genes (B2m, GUSB), which had the relatively stable expression levels.

Statistical analysis

The nonparametric method (Mann–Whitney U test) was used to assess the statistical significance of the differences obtained. Quantitative indicators were tested for normality using the Shapiro–Wilk test. Qualitative indicators were compared using the chi-squared test and the two-tailed Fisher’s test for small samples. The differences between groups were considered significant when \( p < 0.01 \) and \( p < 0.05 \). Data analysis was performed using the Statistica v 8.0, SPSS v.10, and Graph Pad Prism software.

RESULTS

Clinical and instrumental characteristics of patients

Clinical characteristics of the young patients with BP are presented in Table. The average pain intensity value corresponded to 68 mm [48.0–88.0]. Acute pain (lasting for a maximum of 12 weeks) was found in 18% of patients, and 82% of patients had chronic pain. The median disease
duration in the latter was 5 years [2.0–10.0]. Based on BAI values, 82% of patients had moderate and severe functional impairment. The lumbar spine MRI showed the significant disc space narrowing, blurring between NP and AF, and reduced NP signal intensity. At the level of the operated disc, the IVD degeneration grade corresponded to grades 4 and 5 of the Pfirrmann grading system in 66% and 33% of the index group patients, respectively. Herniation was localized at the levels of L4–L5, L5–S1 at a ratio of 36 and 64%, respectively. In 70% of patients, MRI at the level of the operated disc revealed the altered intensity of the bone marrow MR signal on the T2-weighted and STIR (short tau inversion recovery) images, which indicated Modic type 1 changes, the bone marrow edema (45% of patients) (Fig. 1), and Modic type 2 changes, the fatty degeneration (55%), in almost equal proportions. In the control group, Modic changes were found in only one patient (5%) out of 20, and these changes were also associated with severe DDD and asymptomatic IVD herniation. MRI revealed the combination of IVD herniation with erosions of the adjacent vertebral body endplates and Modic changes in 37 index group patients (53.6%). Such a “triple combination” was associated with longer BP duration (years), morning pain, and persistent chronic pain with no “lucid intervals” \( (p < 0.05) \) compared to patients with no erosions of the vertebral body endplates and/ or Modic changes. The index group patients and the controls showed significant differences in the average Pfirrmann DDD grades and the prevalence of Modic changes (4.4 and 2.8 for DDD grades, 70 and 5% for Modic changes; \( p < 0.01 \)). The findings confirm the correlation of Modic changes with IVD herniation and severe DDD.

Abundance of mRNAs of cytokines and vascular endothelial growth factor isoforms in IVD tissues

Of all mRNAs of the studied genes, encoding cytokines and vascular endothelial growth factor isoforms, the TNF\(_\alpha\), IL17, VEGF121, and VEGF165 expression in the cartilage tissue was significantly elevated \( (p < 0.01) \) compared to the control group (Fig. 2). Juxtaposing the mRNA expression levels of all genes, studied in the index group patients, with the IVD degeneration Pfirrmann grades revealed a positive correlation between the expression of TNF\(_\alpha\) and the IVD degeneration grades \( (r = 0.301; p < 0.05) \) (Fig. 3). Despite the fact that the expression of the IL1\(\beta\) mRNA showed no significant differences with the control group, the abundance of this gene in the disc tissue correlated with the disc degeneration severity \( r = 0.37; p < 0.05 \) (Fig. 4).
From the perspective of the IVD matter disorganization progression, it was interesting to assess the cartilage vascularization markers in IVDs with grade 4 or 5 degeneration. The significant negative correlation between the levels of VEGF121 and the IVD degeneration grades \((r = -0.85; p < 0.001)\) was identified for vascular endothelial growth factors, which could indicate the decreased angiogenesis intensity in the discs of patients with the advanced stage DDD.

**Analysis of gene abundance in blood cells**

Further analysis was aimed to identify mRNAs of cytokines and growth factors in peripheral white blood cells. Our study revealed the significantly increased abundance of the genes, encoding interleukins IL1\(\beta\), IL6 \((p < 0.01)\) (Fig. 5). Analysis of the relationship between the expression of the IL6 cytokine mRNA in peripheral blood and the IVD degeneration grade showed the decrease in the cytokine levels in the discs with the advanced IVD Pfirrmann degeneration grades \((r = -0.347; p < 0.05)\), which was indicative of the cytokine significant contribution to degeneration at earlier stages.

Taking into account the high prevalence of Modic changes in the vertebral bodies \((70\%)\) of the index group patients, we assessed the relationship between the cytokine expression levels and the presence of Modic changes. A significant negative correlation between the IL6 levels in blood cells and Modic type 1 and 2 changes was revealed \((r = -0.31; p < 0.05)\), which was indicative of the elevated cytokine expression at the stage of inflammatory bone marrow edema compared to the stage of fatty transformation within the adjacent vertebral bodies. Individuals with a more severe lesion in their functional spinal units, the triple combination (herniation + erosions of the vertebral body endplates + Modic) \((r = 0.401; p < 0.05)\), had a higher expression of IL17 in their peripheral blood compared to individuals having herniation only. Regardless of the low abundance of angiogenic biomarkers in blood of patients with BP, we decided to see whether the vascular endothelial growth factor (isoforms 121, 165, 189) expression levels changed depending on the IVD degeneration grades: significant negative correlations were obtained for all three isoforms \((r = -0.44; -0.33, \text{ and } -0.45, \text{ respectively}; p < 0.05)\).

**DISCUSSION**

Studying the BP pathophysiology in young patients confirmed the involvement of immune and inflammatory mechanisms in disc degeneration. High expression of TNF\(\alpha\) and TNF\(\alpha\) receptors, especially in the AF tissue, in patients with DDD, was also reported by other authors \([17, 18]\). This specific cytokine was described in experiments as an apparent inducer of matrix degradation, especially at the early stages, compared to other mediators \([19]\). The coupled expression of TNF\(\alpha\) and IL17, identified during our study, was found in two studies, conducted by Chinese researchers, and confirmed by the effects of etanercept (inhibitor of TNF\(\alpha\) receptor), which was capable of quenching the entire inflammatory cascade in the disc NP tissue \([20, 21]\). Pathogenetic relationships between the immune inflammation and the disc vascularization, observed during our study, were shown in the overseas human and animal studies \([22, 23]\).

Association of the elevated IL6 gene expression in peripheral blood with Modic changes, and specifically with the inflammatory bone marrow edema grade, was also shown within the framework of the study, performed by Chinese researchers: the expression of IL6 was significantly increased in elderly patients with DDD and Modic type 1 changes compared to patients with Modic type 2 changes \([24]\). The assessment of changes confirmed the fact of the reactive aseptic spondylitis in patients with severe DDD. Detection of the elevated IL17 expression in individuals with the triple combination of lesions in their functional spinal units suggests the existence of the adverse clinical and instrumental phenotype of BP with the immune marker at the systemic level.

It is known that, in accordance with the Pfirrmann grading system, grade 5 of the IVD degeneration is characterized by the dramatically decreased IVD height, hypointense and nonhomogeneous signal from NP, which corresponds to severe, almost total dehydration of NR together with the extracellular matrix disintegration, replacement of the disc central space with type I collagen, and blurring between NP and AF \([25]\). When distinguishing between the natural age-related disc degeneration process and the abnormal disc degeneration, we wish to emphasize the key role of inflammatory markers in the second scenario, being particularly evident and manifesting...
as severe degeneration in young adults [26]. By the age of 4, blood vessels and capillaries of the disc vanish, and the disc becomes a completely avascular structure [27]. As the “low-immune” inflammation develops in the IVd tissues, neovascularization becomes the way of the immunocompetent cells delivery from the systemic blood flow to the cartilage tissue with subsequent activation of catabolic pathways [28] and resorption of the tissue fragment that has fallen out of AF. The vascular endothelial growth factor A (VEGF) is one of the major regulators of angiogenesis. VEGF plays an important role in physiological and pathological neovascularization [29]. The VEGF expression is promoted by the activity of chondrocytes, which form clusters within the NP. In grade 5 DDD, the disc might no longer have the NP along with the rest of the NP cellular content, which is likely to disrupt the angiogenesis stimulation pathway in this settings. These data are consistent with the study, which has shown that the VEGF angiogenic factor expression levels in IVd samples with mild degenerative changes are significantly higher compared to advanced degeneration grades [12]. Taking into account the low reparative capacity of the disc with grade 5 degenerative advanced degeneration grades [12].

Angiogenic factor expression levels in IVd samples with mild angiogenesis stimulation pathway in this settings. These data do not change during the disc degeneration process, BMC Res Notes, 2018; 11: 335 DOI: 10.1186/s13104-018-3441-3.

M. Laboratorija znanij, 2019; 216s.

CONCLUSIONS

The study sheds light on the range of activated genes, which express cytokines, and shows the inflammatory profiles of those in IVd tissues and peripheral blood depending on the DDD severity and the area of the functional spinal unit lesion. The abundance of mRNAs of the studied cytokines and vascular endothelial growth factor expression isoforms in the IVd tissues (TNFα, IL17, VEGF121, VEGF165) was higher in individuals with BP and DDD. The vascular endothelial growth factor expression levels, reflecting the possible processes of neovascularization, dramatically decreased in patients with the terminal grade DDD, both in the IVd tissues and in peripheral blood. However, the levels of TNFα and IL1β cytokines in the cartilage tissue positively correlated with the severity of the IVd degeneration, which was in line with the concept of immune inflammation, associated with DDD. The IL6 gene expression levels in white blood cells turned out to be increased in patients with Modic changes and were to a greater extent associated with inflammatory bone marrow edema in adjacent vertebral bodies at the level of the compromised segments, and the levels of IL17 turned out to be increased in patients with a combination of herniation, erosions of the adjacent vertebral body endplates, and Modic changes. The findings would help to identify the molecular targets and new directions for the anti-inflammatory and reparative therapy of DDD.

References

Currently, age-related macular degeneration (AMD) is among the leading causes of the irreversible central vision loss, occurring predominantly in the elderly. According to literature, the prevalence of AMD among individuals aged 45–85 is 8.96%, with a predominance of the early stages of the disease (8.01%) [1].

In accordance with the generally accepted classification of the Age-Related Eye Disease Study (AREDS), AMD is subdivided into four categories. The AREDS Category 1 (no AMD) is characterized by no drusen or small drusen of less than 63 μm in diameter. The AREDS Category 2 (early stage AMD) corresponds to numerous small drusen, and/or a small number of medium-sized drusen of 63–124 μm in diameter, or initial changes in the retinal pigment epithelium (RPE). The AREDS Category 3 (intermediate stage AMD) is characterized by numerous medium-sized drusen, and/or one large druse of more than 125 μm in diameter, or RPE atrophy, not affecting the retinal center. The AREDS Category 4 (late stage AMD) is characterized by atrophy of RPE and choroidal capillaris layer in the retinal center, and/or neovascular maculopathy [2].

Drusenoid pigment epithelial detachment (DPED), in which RPE and its basement membrane are separated from the inner collagen layer of the underlying Bruch’s membrane due to formation and accumulation of drusenoid material, represents the intermediate stage of AMD. This form of PED was originally described by A. G. Casswell in 1985 [3, 4].

To date, pathophysiological mechanisms of DPED have not been fully explored. It is believed that this disorder results from the gradual increase and merging of the large number of pre-existing soft drusen, which results in the focal retinal detachment of at least 350 μm in diameter. With increasing DPED, the prolonged dissociation between the RPE cells and the Bruch’s membrane/choroidal capillaris complex leads on the one hand to the RPE cells’ migration into the outer retinal layer,
and on the other hand to these cells’ apoptosis. The long-lasting DPED, associated with the decreased number and alteration of RPE cells, results in photoreceptor dysfunction and subsequent atrophy. Eventually, in case of DPED collapse, the zone of complete RPE atrophy is registered, with the outer neurosensory retina atrophy [5, 6].

In case of the long-lasting DPED with its subsequent regression, the most common symptoms are as follows: decreased visual acuity, metamorphopsia, difficulty or inability to read up close. However, RPE detachment, identified at an early stage, is characterized by preserved visual functions [5–8].

The use of the spectral-domain optical coherence tomography (SD-OCT) in morphometric assessment of the retinal layer changes in patients with DPED made it possible to distinguish the risk factors for the disease progression, such as height, volume, and diameter of the detached RPE, as well as the presence of intraretinal and subretinal hyperreflective material above the RPE detachment. These risks were studied with regard to DPED located within 500 μm of the fovea [6, 7].

Currently, there are no efficient and safe treatment methods for DPED. If this disorder is diagnosed, the management of patients is in most cases limited to follow-up. However, progression to late AMD is observed in the natural course of the disease within 5 years (42% of cases), with the development of geographic atrophy in the macular zone (19% of cases), which results in irreversible vision loss, as well as in declined quality of life, disability, and poor work ability prognosis [3, 7, 8].

Conservative treatment, which involves the use of antioxidant medications, vitamins and minerals, fails to prevent the AMD progression to advanced stages, which was confirmed by research, and requires the constant use of these medications throughout the patient’s life [9].

The majority of studies on assessing the efficacy and safety of using laser technologies in patients with intermediate AMD were focused mostly on finding ways to slow down the disease progression and to reduce the number of various soft drusen types [10–15].

With regard to the high risk of DPED progression to late AMD, with subsequent significant decline in the patients’ visual functions, finding the efficient and safe treatment method for this disorder is relevant. The study was aimed to demonstrate and assess the long-term morphological and functional effects of multimodality laser therapy in a patient with DPED, observed during the 5-year follow-up period.

Clinical case

In June 2017, patient Sh, aged 74 presented with complaints of diminished visual acuity in both eyes, metamorphopsia, and trouble with close-up reading using both eyes at the Research Center of Ophthalmology, Pirogov Russian National Research Medical University. According to medical history, the above symptoms have been troubling the patient for a year. In 2015, cataract surgery, phacoemulsification and intracocular lens implantation, was performed in the right and left eye.

Once admitted to the Center, the patient underwent a comprehensive ophthalmic examination, which included the standard diagnostic tests (visometry for uncorrected visual acuity (UCVA) and best corrected visual acuity (BCVA), indirect ophthalmoscopy with a MaxField indirect lens (Ocular Inc.; USA), specific assessment methods (microperimetry (MAIA micropirometer, CenterVue Inc.; Italy), SD-OCT, and optical coherence tomography angiography (OCTA) performed using a Spectralis HRA+OCT, OCT-2 module at 85,000 Hz (Heidelberg Engineering, Inc.; Germany)).

Laser photocoagulation was performed with the IRIDEX IQ 577 ophthalmic laser system (IRIDEX Corporation, MountainView; USA).

During the initial assessment the patient complained of diminished visual acuity in both eyes, metamorphopsia, and trouble with close-up reading using both eyes; UCVA of the right eye (OD) was 0.3; BCVA was 0.7 OD, and those of the left eye (OS) were 0.2 and 0.7, respectively. According to microperimetry, the average central retinal sensitivity was 23.3 dB OD and 21.6 dB OS.

Slit lamp biomicroscopy and indirect ophthalmoscopy in both eyes (OU) showed that the anterior segment was intact; the well-centered Intracocular lens was in the capsular bag. The optic disc was pale pink, with well-defined margins. Hypertensive angiopathy was revealed. There were numerous prominent small yellowish round-shaped lesions with well-defined margins in the macular zone. In the foveal zone, expanding downwards into the parafoveal region, the there was a large prominent pale-yellow oval-shaped lesion 1.5 times the diameter of the optic disc with blurry margins and redistribution of pigment, surrounded by large yellowish lesions with blurry margins. Retinal periphery was intact.

SD-OCT OD revealed macular deformation. In the foveal zone, the RPE detachment was visible with the height of 166 μm and the length of 1126 μm, with downward expansion into...
the parafoveal region with the height of 218 μm and the length of 1852 μm, with homogeneously hyperreflective deposits, together with the undulating RPE line, and the coalescent soft drusen up to 125 μm in diameter. Subretinal hyperreflective deposits were found above the detached RPE (Fig. 1A).

SD-OCT OS revealed macular deformation. In the foveal zone, the RPE detachment was visible with the height of 173 μm and the length of 2348 μm, with downward expansion into the parafoveal region with the height of 190 μm and the length of 1039 μm, with homogeneously hyperreflective deposits, together with the undulating RPE line, and the coalescent soft drusen up to 125 μm in diameter. Subretinal hyperreflective deposits were found above the detached RPE (Fig. 1B).

OCTA image (OU) analysis revealed no evidence supporting the choroidal neovascularization.

The following diagnosis was established based on the patient’s complaints, medical history, and the results of the comprehensive ophthalmic examination: OU Age-related macular degeneration, dry form, intermediate stage (according to AREDS classification). Drusenoid pigment epithelial detachment. Pseudophakia.

It was decided to perform the multimodality laser therapy, which included grid laser photocoagulation with the lowest possible energy settings to form the first degree coagulum. After 10 days the patient received three sessions of micropulse laser therapy (every four weeks). Grid laser photocoagulation was performed using the following settings: wavelength 577 nm, power 50 mW, pulse duration 0.1 s, spot size 100 μm; coagula were applied throughout the area of the detached RPE, except avascular zone, with a spacing of 150 μm. Micropulse laser therapy was performed with the following settings: wavelength 577 nm, burst duration 30 ms, micropulse duration 50 μs, pulse ratio 4.7%, spot size 100 μm, power 50 mW; coagula were applied throughout the area of the detached RPE, the avascular zone was avoided.

One month after the multimodality laser therapy the patient reported the improvement of visual acuity, however, metamorphopsia persisted.

Ophthalmic examination showed that UCVA OD was 0.3, BCVA OD improved to 0.8, UCVA OS had improved to 0.3, and BCVA OS was 0.7. According to micropirometry, the average central retinal sensitivity had improved to 24.1 dB OD, and to 23.0 dB OS. Slit lamp biomicroscopy and indirect ophthalmoscopy OU revealed no improvement: in the foveal zone, expanding downwards into the parafoveal region, there was still a large prominent pale-yellow oval-shaped lesion 1.5 times the diameter of the optic disc with blurry margins and redistribution of pigment, surrounded by the large yellowish lesions with blurry margins; the lightly pigmented coagula were visible across the surface of the detached RPE.

According to SD-OCT OD, the macular deformation persisted, and the RPE detachment reduction was observed. In the foveal zone, the height of the RPE detachment reduced from 166 to 164 μm, and the RPE detachment length reduced from 1126 to 1081 μm. In the lower parafoveal region the height reduced from 218 to 211 μm, and the RPE detachment length reduced from 1852 to 1826 μm. The homogeneously hyperreflective deposits, together with the undulating RPE line, and the coalescent soft drusen up to 125 μm in diameter were found below the detached RPE. Subretinal hyperreflective deposits were found above the detached RPE (Fig. 2).

According to SD-OCT OS, the macular deformation persisted, and the RPE detachment reduction was observed. In the foveal zone, the height of the RPE detachment reduced from 173 to 154 μm, and the RPE detachment length reduced from 2348 to 2286 μm. In the lower parafoveal region the height reduced from 190 to 171 μm, and the RPE detachment length reduced from 1039 to 982 μm. The homogeneously hyperreflective deposits, together with the undulating RPE line, and the coalescent soft drusen up to 125 μm in diameter were found below the detached RPE. Subretinal hyperreflective deposits were found above the detached RPE (Fig. 2B).

Three months after the laser treatment on the follow-up examination the patient reported the improvement of visual acuity, no metamorphopsia, and no trouble with the close-up reading. Ophthalmic examination showed that UCVA OD and OS was stable (0.3); BCVA OD and OS was 0.8. The average central retinal sensitivity was stable (24.1 dB OD, 23.4 dB OS). Slit lamp biomicroscopy and indirect ophthalmoscopy OU revealed the following features: small yellowish round-shaped lesions with well-defined margins in the macular zone, sporadic large yellowish lesions with blurry margins, redistribution of pigment; the lightly pigmented coagula were visible, the DPED was completely regressed.

SD-OCT OD and OS revealed the restored macula, the completely regressed DPED, undulating RPE line, sporadic soft drusen, and accumulation of subretinal hyperreflective deposits (Fig. 3A, B).

A year after the multimodality laser therapy the patient had no complaints. Ophthalmic examination showed that UCVA OD and OS was 0.3, BCVA OD had reached 0.9, and BCVA OS was stable (0.8). According to micropirometry, the average central retinal sensitivity OD improved to 25.7 dB, and the average central retinal sensitivity OS was stable (23.9 dB). Slit
Fig. 3. Spectral-domain optical coherence tomography image of the fovea. A. Right eye: macula remains intact, undulating RPE line, sporadic hard drusen (blue arrow), accumulation of subretinal hyperreflective deposits (green arrow). B. Left eye: macula remains intact, undulating RPE line, sporadic hard drusen (blue arrow), accumulation of subretinal hyperreflective deposits (green arrow).

Fig. 4. Spectral-domain optical coherence tomography image of the fovea. A. Right eye: macula remains intact, undulating RPE line (orange arrow), sporadic hard drusen (blue arrow). B. Left eye: macula remains intact, undulating RPE line (orange arrow).

A number of authors reported the cases of using photodynamic therapy with verteporfin [16], intravitreal injections of angiogenesis inhibitors [17], high-dose statin therapy [18] for treatment of DPED. These methods contributed to the reduction and regression of RPE detachment throughout the one-year follow-up period. However, the long-term efficacy and safety of the methods had not been explored.

The clinical trials on using the laser technologies in patients with the intermediate stage AMD were focused on assessing the feasibility of reducing the number of drusen and slowing the progression of the disease; in the majority of cases the follow-up period was three years. According to a number of authors, encouraging results in the form of the reduced drusen volume were achieved when using laser photocoagulation. However, side effects can develop when using the high energy laser treatment, such as photoreceptor layer death, formation of central and paracentral scotomas, progression to geographic atrophy, choroidal neovascularization, and subretinal fibrosis [10, 11]. Low power mode laser therapy was used in the reported case in order to prevent the listed above complications and provide a positive clinical impact.

Currently, a number of subthreshold laser therapy methods are used allowing one to selectively and precisely affect the RPE.
cells only and thus reduce the risk of adverse alterations in the retina and chorioriapilaries. The use of these laser therapy methods in patients with the intermediate stage disorder reduced the number of drusen, contributed to drusen resorption and visual acuity improvement, but did not seem to have much effect in terms of slowing the disease progression to geographic atrophy or choroidal neovascularization. According to the LEAD study, no correlations between the use of laser technologies and the complications, such as retinal hemorrhages, nascent geographic atrophy, and photoreceptor layer atrophy, were revealed [12, 13].

We used a combination of two laser procedures with different mechanisms of action in order to improve the morphological and functional treatment outcome in patients with DPED. The first step was grid laser photocoagulation aimed at activating the RPE pumping function, as well as at improving the retinal architecture and enhancing the structural support provided by Muller cells through the chorioretinal adhesion creation. The use of micropulse laser therapy allowed us to selectively target the RPE cells avoiding damage to the retinal neuroepithelium. The production of factors, maintaining and enhancing regeneration, prolonging the processes of the retinal architecture restoration and visual function improvement, was considered the main therapeutic effect.

Thus, the use of the proposed multimodality laser treatment for DPED made it possible not only to achieve good morphological and functional results, but also to maintain this level throughout the 5-year period.

CONCLUSION
The proposed multimodality laser treatment method allowed us to repair the pigment epithelial detachment (DPED), restore the retinal architecture, and improve the visual functions. The results achieved showed the potential of low-level laser microsurgery for restoring the macular morphological and functional parameters in the presence of the age-related dystrophic process. With further study, this technology may increase the potential for treatment of the intermediate age-related macular degeneration.

Macular retinal folds are a rare yet grave complication of surgical rhegmatogenous retinal detachment repair. Clinical symptoms vary depending on the location and severity of folding. Folded located in the periphery of the ocular fundus can be asymptomatic, but macular retinal folds cause diminished visual acuity and metamorphopsia. Currently, the most effective treatment for retinal folds is repeat surgery. Its serious disadvantage is the risk of complications in the early postoperative period, including hemophthalmia, inflammation, secondary glaucoma, cataracts, RRD recurrence, macular tears, retinal vascular occlusion, etc. The clinical case described below demonstrates the potential of combination laser therapy for the treatment of macular retinal folds based on the use of modern diagnostic and therapeutic methods.

Inner retinal folds involve the inner retinal layer and appear on OCT as a pronounced distortion of the retinal profile presenting as internal limiting membrane to internal limiting membrane apposition. Outer retinal folds appear as multiple small vertically oriented hyperreflective lesions over the retinal pigment epithelium (RPE), extending into the outer nuclear layer [11, 12].

According to the literature, there is no unified treatment strategy for retinal folds. The outcomes also vary, from complete resolution of the fold and visual function recovery to partial regression with minimal or moderate vision recovery to severe irreversible retinal damage. In most cases, macular retinal folds persist causing irreversible loss of visual acuity and metamorphopsia [3–6, 10, 13]. Besides, patients with previously stable retinal folds are reported to develop late recurrent retinal detachment resulting from proliferative vitreoretinopathy, which in turn may be caused by retinal folds [5].

Considering the high risk of intra- and postoperative complications after repeat vitreoretinal surgery, it is important to develop a non-invasive pathogenetic treatment for retinal folds that would minimize potential damage to the sensory retina.

Currently, laser technologies are being increasingly used for treating retinal pathology. Retinal grid laser photocoagulation with spots applied in the checkerboard pattern and spaced > 1 spot size apart is a popular technique for enhancing the structural support provided by Müller cells and improving retinal architecture by creating chorioretinal adhesions. Active and sustainable retinal tissue regeneration can be achieved through micropulse laser therapy [14, 15]. Below we report the use of combination laser therapy for the macular retinal fold developing in the late postoperative period after surgical RRD repair.

Clinical case

In October 2020, a male patient presented with complaints of metamorphopsia and diminished visual acuity in the right eye at the Research Center of Ophthalmology, Pirogov Russian National Research Medical University. According to his medical records, in August 2020 the patient had undergone microinvasive subtotal vitrectomy with intravitreal perfluorocarbon liquid (PFCL)/gas injection and received an intraocular lens implant for RRD in the right eye.

Once admitted to the Center, the patient underwent a comprehensive ophthalmic examination. Standard diagnostic tests included visometry for uncorrected visual acuity (UVA) and best corrected visual acuity (BCVA) and indirect ophthalmoscopy with a MaxField indirect lens (Ocular Inc.; USA). In addition, optical coherence tomography was performed using a Spectralis HRA+OCT platform (Heidelberg Engineering GmbH; Germany). Laser photoocoagulation therapy was delivered using a VISULAS Trion work laser station (Carl Zeiss; Germany) operated at 577 nm wavelength.

During the initial examination the patient complained of metamorphopsia and diminished visual acuity in his right eye. UVA of the right eye (OD) was 0.05; BCVA was 0.7 for OD and 1.0 for the left eye (OS).

Ophthalmic OD biomicroscopy revealed that the anterior segment was intact and the intraocular lens was well centered. The optic disc was pale pink, with well-defined margins. A PFCL bubble was visible peripapillarily on the nasal side. Pronounced retinal folding ending with a subretinal PFCL bubble extended from the temporal optic disc margin toward the 8 o’clock plane (Fig. 1). The caliber of the retinal vessels was unchanged. Cellophane maculopathy also known as epiretinal membrane was visualized paravasally along the course of the superior and inferior temporal arcades. Laser-sealed retinal breaks were present in the upper quadrant of the peripheral.

Of all OCT images of the right eye, the most informative in terms of postoperative dynamics were scan A (Fig. 2A) and the next scan B passing 250 μm higher, closer to fovea (Fig. 2B).

Considering the patient’s complaints, his medical history and the results of the comprehensive ophthalmic examination, the following diagnosis was established: operated RRD in the right eye complicated with macular retinal folding; epiretinal membrane; avitria; artiphakia.
In December 2020, a decision was made to perform laser microsurgery on the patient in order to restore the architecture of the macular zone, flatten the folds, and improve the morphology and function of the retina. The combination treatment was delivered in several steps. In the first step, the patient underwent grid laser photocoagulation. The burns were applied along the course of the retinal fold and under it in the checkerboard pattern in 3 to 4 rows depending on the severity of the fold; the avascular zone was avoided. The laser workstation was operated at the lowest possible settings to ensure the lowest intensity of coagulation: power 50 mW, pulse duration 0.05 s, spot diameter 100 μm, wavelength 577 nm, spacing 150 μm. Single laser spots were applied paramacularly along the upper edge of the macula. Additionally, laser coagulation was performed on the epiretinal membrane along the course of the superior and inferior temporal vascular arcades. In the second step, the patient received 3 sessions of micropulse laser therapy (wavelength 577 nm, burst duration 30 ms, micropulse duration 50 μs, pulse ratio 4.7%, spot diameter 100 μm, power 50 mW).

Two months after surgery, the comprehensive ophthalmic examination revealed a slight improvement, although no significant morphological and functional changes were observed.

Four months after the intervention, the patient reported a significant reduction of metamorphopsia. His UVA and BCVA had improved to 0.2 and 0.7, respectively. Ophthalmic biomicroscopy of the right eye revealed the intact anterior segment and the well-centered intraocular lens. The fold in the central zone had flattened and was now 921 μm wide (Fig. 3B). Paramacularly and along the retinal fold, weakly pigmented coagulation spots were visible. The caliber of the retinal vessels was unchanged. Paravasally, weakly pigmented coagulation spots were present in the epiretinal membrane area. Changes in the retina can be clearly seen on the follow-up OCT scans (Fig. 3A, B).

Six months later on another follow-up examination the patient reported the absence of metamorphopsias in the right eye; UVA: 0.2; BCVA: 0.7. On ophthalmic biomicroscopy the anterior segment was intact, the intracocular lens was well-centered. The optic disc was pale pink, with well-defined margins. The retinal folds had unfolded, the dominant retinal fold was not visualized. A slight undulation (up to 1.371 μm in width) was visualized on the retinal surface where retinal folding had been previously observed (Fig. 4B). Weakly pigmented coagulations spots were present in the epiretinal membrane area, except for the avascular zone. Changes in the retina can be clearly seen on the follow-up OCT scans (Fig. 4A, B).
Clinical case discussion

Retinal folds are a clinically important complication of surgical RRD repair. Few attempts have been reported to surgically treat retinal folds, including macular folds of different etiology [2, 16, 18]. There is no clear guidance on the timeframe and indications for repeat surgery. Experiments conducted in vivo have demonstrated that apoptosis of the photoreceptor layer and thinning of the outer nuclear layer start a week after macular translocation [18].

Repeat surgery is often delayed because retinal folds can be diagnosed no sooner than gas injected in the vitreous cavity is reabsorbed. Another reason is the risk of complications in the early postoperative period, including hemophthalmia, inflammation, secondary glaucoma, cataracts, RRD recurrence, macular tears, retinal vascular occlusion, etc. [11, 17, 19].

This study describes an alternative to vitreoretinal surgery: a combination laser therapy involving 2 interventions with different mechanisms of action. The proposed treatment method has indisputable advantages like non-invasiveness, low injury rate, and lack of serious complications or adverse effects. Due to the gradual topographically directed effect of grid laser photocoagulation, we were able to unfold the retina, restore the position of the macula and its functional and morphological characteristics. Paramacular tissues (the dominant retinal fold) flattened out, and retinal thickness and structural organization were recovered. The macular profile shifted to its normal microtopographic position, becoming more clearly visible on OCT scan B (Fig. 3B); foveal depth and width also normalized. The patient’s metamorphopsia (distorted vision) resolved, his uncorrected visual acuity and the ability to use binocular vision improved. In addition, micropulse laser therapy prolonged tissue regeneration.

Summing up, the coagulation effect of laser energy applied locally to achieve controlled retinal stretching causes shifting of retinal microlayers, reorganizing the architecture of the macular zone. Low-dose exposure of the affected retinal zones to micropulse laser energy activates prolonged regeneration. The proposed method produced pronounced morphofunctional effects on macular retinal folding, which develops in the late postoperative period after retinal detachment repair.

CONCLUSION

The proposed combination laser treatment of macular folds developing in the late postoperative period after RRD repair significantly improved the morphofunctional characteristics of the eye. The application of transpupillary laser surgery to ophthalmological practice broadens the arsenal of methods for noninvasive correction of RRD associated with macular retinal folds.

The study demonstrates the potential of laser microsurgery (at the micron level) for correcting the damaged microtopography and microarchitecture of the macular retina, ensuring recovery of normal functions of the eye.

An injury to the knee ligament apparatus is a pathology that involves one or more ligaments of the knee joint [1]. It is more prevalent among young able-bodied working-age men actively engaged in sports and exercise and is one of the most common traumatic and orthopedic injuries that compel the patient to seek medical help [1, 2]. The most common injury to the capsular ligament apparatus is an anterior cruciate ligament tear, affecting 30–35 people per 100,000 population [1]. Cruciate ligaments are fibrous bands of connective tissue that connect the femur and the tibia and limit excessive tibial mobility [3].

Most often, anterior cruciate ligament injuries are noncontact and occur during sudden knee joint rotation with the foot firmly planted [1, 4]. Many isolated ligament injuries are consequences of sports injuries caused by a rotational mechanism [5]. The following procedures are used to establish a diagnosis of anterior cruciate ligament tear: history taking, the Lachman test, the Anterior and posterior drawer tests of the knee, radiography of the knee joint (antero- and lateral views), and magnetic resonance imaging (MRI) of the knee joint [4]. Motion capture analysis (MCA) of gait provides valuable diagnostic data about the patient’s locomotion patterns. It

relies on the computer analysis of movements in which image acquisition is performed in a cableless, noncontact fashion [6]. Today, passive markers are widely used in clinical motion capture analysis. Passive markers are reflective sensors that are attached to the patient’s body; the signals emitted by the sensors are captured by the video camera. The acquired data are transmitted to the computer for further processing. Finally, a report is generated that is subsequently used to analyze the linear and angular kinematics of the patient’s movements [7].

MCA requires that, since a plane is defined by 3 points, there should be at least 3 reflective markers in the field of view of at least 2 cameras [8]. To measure the physical characteristics of the studied body segments, calibrating markers are attached to the subject. So far, reference standards have been elaborated for movements of the foot, tibia, femur, pelvis, spine, wrist, forearm, and shoulder [9].

At present, MCA is being actively used to uncover the mechanisms of noncontact injuries to the anterior cruciate ligament of the knee joint [10]. 3D MCA has been proposed for adoption into clinical practice as a tool for monitoring rehabilitation in patients with knee joint injuries and assessing the risk of re-injury [11]. The clinical case described below illustrates a personalized MCA-based assessment of locomotor function in the patient with anterior cruciate ligament tear.

**Clinical case**

Patient I., aged 21 years, was diagnosed with a complete anterior cruciate ligament tear of the left knee joint and a partial posterior cruciate ligament tear. On January 19, 2021 the patient...
underwent arthroscopy of the left knee joint, resection of the remnant anterior cruciate ligament tissue, reconstruction of the anterior cruciate ligament with a peroneus longus autograft and autograft fixation with 19 PEEK Interference Screws (Arthrex; USA). The postoperative course was unremarkable. The patient received conservative treatment, which included antibiotics, analgesics, anticoagulants, and dressings. The knee joint was immobilized with a knee brace; the patient was using crutches for support when walking. On discharge, the patient’s condition was satisfactory.

Preoperative MRI performed on December 3, 2020 revealed an impression fracture of the lateral femoral condyle; trabecular edema of the lateral tibial condyle, the intercondylar area and the medial femoral condyle; synovitis and suprapatellar bursitis; MR features of injury to the anterior cruciate ligament and ligamentitis of the medial collateral ligament; moderate degenerative changes of the anterior and posterior horns of the medial meniscus; periarticular soft tissue edema.

Subject V., aged 22 years, had no health complaints regarding their musculoskeletal system, no medical history of lower limb surgery or injury and was comparable with patient I in terms of their anthropometric characteristics.

The patient and the healthy subject were tested at the Laboratory of MCA at the Federal Siberian Research and Clinical Center (FMBA, Russia) using a Vicon Motion Capture Systems (Vicon; UK). The system consisted of 12 infrared T20 video cameras, 3 force plates, a Vicon GigaNet connectivity device, a computer with installed software for video signal capture and processing (Nexus ver. 1.7.15) and software for generating reports (Polygon ver. 3.5.1).

The testing included several stages. First, anthropometric measurements were taken to map the sizes of the patient’s body segments to the computer model. Then, reflective markers were attached to the subject’s bony landmarks. The patient and the subject were asked to walk at their usual speed on 3 force plates. During the test, the video cameras captured the spatial positions of the markers and the force plates recorded the ground reaction force. Each participant performed at least 10 gait cycles on 3 force plates.

The following changes in gait characteristics were observed in the patient with an anterior cruciate ligament tear vs the healthy subject.
Table 3. Mean knee flexion and extension angles and amplitudes during one gait cycle in the patient with injuries to the knee ligament apparatus and the healthy subject

healthy subject: significantly lower cadence and velocity, shorter step and stride lengths, longer step and stride times, longer single and double support phases, shorter toe-off phase for both lead and contralateral legs (Table 1).

The step width was significantly greater in the patient after anterior cruciate ligament reconstruction than in the healthy subject. The initial contact time for the contralateral leg did not differ between the patient and the healthy subject.

The changes detected during the test suggest a gait pattern disturbance in the patient characterized by a slower, shorter, wider step with longer step intervals. We think that these changes are associated with 2 factors. First, the gait pattern may have undergone pathologic changes in the early postoperative period when the patient had to use crutches for locomotion and wear braces. Second, proprioception in the operated knee joint was impaired, which affected coordination in and between the muscles surrounding the knee joint.

3D MCA can be used to measure the amplitude of movement for different body parts at different stages of gait cycle and to compare the obtained data with the podometry data. The amplitudes of movement of the hip, knee and ankle joints observed in the patient and the healthy participant are shown in the graphs (Fig. 1–4). The analysis revealed that hip flexion and extension amplitudes in the operated (left) leg were narrower than in the right leg (Fig. 1, Table 2).

The analysis showed that the amplitude of left lower leg flexion and extension at the knee joint during one gait cycle was reduced in the patient, as compared with the healthy subject (Fig. 2, Table 3). Ankle flexion and extension amplitudes during walking were smaller for the operated leg than for the right healthy leg (Fig. 3, Table 4).

The amplitude of movement in the lower leg joints was reduced due to the impaired gait pattern and a reduction in the passive and active range of motion in the lower leg, which again could be explained by immobilization after surgery (the need to wear an orthosis/brace) and the lack of adequate movement stereotype. The range of motion in the joints may be affected by the choice of the donor site for anterior cruciate ligament reconstruction. Further research is needed to test this hypothesis.

We also found that the degree of left knee joint rotation was significantly lower than in the right knee joint (Fig. 4, Table 5). Rotation asymmetry in the knee joint was observed in the healthy subject, too, but it was slight.

Discussion clinical case

A study reported the use of MCA during a single leg hop test for assessing recovery of static and locomotor function in athletes after anterior cruciate ligament repair [12]. The following parameters were evaluated: knee flexion at initial contact, peak knee flexion, knee flexion range of motion, and knee valgus range of motion in the frontal and sagittal planes. The speed and rhythm of the gait were not studied. The authors concluded that MCA could be recommended as a simple and accurate method for assessing knee joint stability and predicting changes of returning to sports after anterior cruciate ligament reconstruction [12].

Another study employed MCA to assess the risk of injury in athletes following anterior cruciate ligament reconstruction [13]. The researchers performed the motion analysis of leg movements and assessed stability of the knee joint during walking, running, kicking the ball with moderate force and ball lashing. In addition to the speed and rhythm of gait, the researchers measured the ratios of flexion and extension angles in the operated and healthy knees during running and ball kicking. The angular characteristics of movements were not studied. It was concluded that MCA could be used as independently and as a complementary tool for gait analysis [13].

Another study was conducted in female athletes with anterior cruciate ligament injury; MCA was applied to analyze the mean knee flexion and the mean valgus angles during the initial contact, the internal and external rotation angles of the knee joint, and the mean peak vertical ground reaction force. The anterior cruciate ligament injury was attributed to a combination of valgus loading and internal knee joint rotation [14].

In another publication, the mechanisms of a slip-catch injury to the anterior cruciate ligament were investigated using MCA. The following parameters were analyzed: the knee
flexion angle, the tibial internal rotation angle, and the mean knee valgus angle. Speed, rhythm and angular parameters of motion in the hip and ankle joints were not studied. The study concluded that valgus loading, internal knee joint rotation and abduction were significant contributors to the slip-catch injury [15].

Changes in movement characteristics observed in the operated knee (reduced hip, knee and ankle flexion and slip-catch injury [15].

CONCLUSION

3D MCA is an informative method for the analysis of subtle changes in the biomechanics of walking in patients with anterior cruciate ligament injuries. The method generates valuable data about the amplitude and angular parameters of motion, and the speed and rhythm of gait.

Further research is needed to clarify how long the pathologic changes to the gait may persist and whether they can be managed through rehabilitation.

В клинической практике для диагностики избыточной массы тела и ожирения традиционно используют антропометрический метод. Ожирение — это избыточное развитие прежде всего висцеральной и подкожной жировой ткани, которое может быть диагностировано методом биоимпедансометрии (BIA). Целью исследования было оценить роль биоимпедансного анализа состава тела в диагностике нарушений физического развития детей и подростков. Проведено антропометрическое и биоимпедансометрическое обследование 431 самарского школьника I и II групп здоровья в возрасте 12–16 лет (230 мальчиков и 201 девочка). Анализ результатов проводили по региональным шкалам регрессии, показателю BAZ и доле жировой массы. Результаты оценивали по шкалам регрессии выявили 22,61% мальчиков и 23,43% девочек с избыточной массой тела, при этом более 2/3 исследуемой группы детей имели нормальное физическое развитие. Показатель BAZ выявил значимо больше число детей с избыточной массой тела среди мальчиков (25,7%), чем среди девочек (11,5%, p < 0,01). Отклонения доли жировой массы по данным BIA определялись не только среди детей с дисгармоничным физическим развитием, но и среди 60% детей с нормальной массой тела. При этом выявленные по шкалам регрессии отклонения массы тела данным BIA подтверждены в большинстве случаев, нежели диагнозы избыточной или недостаточной массы тела, полученные по индексу BAZ. Исходя из этого, первоочередным для своевременной диагностики нарушений нутритивного статуса у детей, может быть использован антропометрический анализ с применением региональных шкал регрессии. Для подтверждения избыточной массы тела и ожирения у детей, а также для дальнейшей терапии необходим достоверный метод оценки жировой составляющей организма, в качестве которого может выступать метод BIA.

DOI: 10.24075/vrgmu.2021.062
Physical development is an essential criterion of the comprehensive health assessment, performed during the routine check-ups of children and adolescents, which reflects the impact of the complex set of factors [1–3]. According to the research, carried out in the regions of our country, a little over 60% of boys and about 67% of girls are characterized by the harmonious physical development. Dis harmonious physical development is due more to the excess body weight, which is found in 18% of boys and 14% of girls [3–6]. The importance of the excess body weight issue is defined by high prevalence of pathological conditions and complications, high risk of obesity with comorbidities, resulting in the young patients' disability [7, 8]. Traditionally, anthropometric methods involving the analysis of the results obtained by the standard measurement of height and body weight, as well as the calculation of the estimation indices, mostly the body mass index (BMI), is used in clinical practice for the diagnosis of excess body weight [9]. The World Health Organization has developed the BMI maps for children and adolescents aged 2–19 to analyze the calculation results [10]. In addition, the weight to height ratio could be assessed using the regression scores, centile charts, and sigma deviations [10].

Obesity is an excess development of the visceral and subcutaneous adipose tissue rather than the total body fat mass [11–13]. Despite the positive correlation between the BMI and the child's anthropometric data, BMI does not reflect the actual body fat percentage, which is continuously changing in children during various age periods. The example of such period is the childhood intensive period of growth, when BMI may indicate the normal weight to height ratio, and the actual fat mass may be underestimated, which could result in the erroneous interpretation of the study results [8, 14]. In this regard, the use of the anthropometric method only as the diagnostic criterion of overweight and obesity could be questionable. Moreover, low comparability of the research results may be the consequence of the use of different anthropometric diagnostic parameters [3, 6, 9, 15].

In contrast, biophysical methods ensure higher accuracy of the results when measuring the body weight characteristics. Bioimpedance analysis (BIA) of body composition has become the most widely used method. BIA is based on the difference between the resistance (impedance) values of the fat mass and fat-free (lean) body mass, as well as on the total body water and body composition. The assessment results are used in clinical practice to analyze the nutritional status and nutrient intake, the risk of metabolic syndrome, obesity, disorders of cardiovascular system and other systems of the body; the results are also used as the diagnostic criteria for estimation of the therapy efficacy in patients with various diseases [16–19]. For its part, comparison of the results of biopmepedance measurement of the fat mass as a percentage of the body mass and BMI in healthy children shows that a broad range of the body fat percentage values corresponds to the same BMI values [20]. Thus, the use of data, obtained by BIA of body composition, in combination with the anthropometric data as the diagnostic criteria for the abnormal patterns of the children's physical development needs to be studied.

The study was aimed to assess the role of BIA of body composition in the diagnosis of the physical development disorders in children and adolescents.

**METHODS**

The cross-sectional cohort study of the prevalence of physical development disorders among the secondary school students of the general educational institutions in Samara based on the anthropometric and bioimpedance measurement data was carried out. The children were examined at their educational institutions from March to May 2021, with interruptions for spring vacation (March 22–28) and public holidays. A total of 431 children aged 12–16 (the median age was 13 years 8 months) were examined: 230 boys (53.4%) and 201 girls (46.6%) of grades 5–9 of the general education schools.

Inclusion criteria: age 12–16 years, permanent residence in the territory of Samara region; compliance with the health status group I or II based on medical documentation; informed consent to the study participation submitted by parents (legal representatives). Exclusion criteria: age at the time of examination less than 11 years 6 months and one day or over 16 years 6 months and one day; chronic disorders; taking medications; prominent limb swelling; permanent residence outside of Samara region; no informed consent to participation or refusal of participation provided by parents (legal representatives).

Anthropometric indicators were measured in the following way: body height was measured with the MSK-233 stadiometer (Medstalkonstruktsiya; Russia) to within 5 mm, and body weight was measured with the VEM-150-A1 medical scales (Massa-K; Russia) to within 50 g. Body composition was defined by BIA using the АВС-01 internal environment analyzer (Massa-K; Russia) to within 50 g. Body composition was controlled in the rooms, where the examination was carried out. The children's physical development was assessed based on the height to weight ratio in two different ways. The first method involved estimation of physical development with the use of the regional regression models, fitted with body weight as dependent variable and height, developed for Samara region [21]. The second method involved calculating the BMI for age Z-score (BAZ), and the resulting values were analyzed in accordance with the WHO standards [10] using the WHO AnthroPlus software (2008) (WHO; Switzerland) [22]. BMI was calculated as the child's weight (kg) divided by the square of height (m2). Nutritional status was further assessed based on the data obtained by BIA of body composition, the body fat percentage (%BF). The criteria for the estimation of the results are presented in Table 1.

The raw data were acquired and stored using the Microsoft Excel 2013 software (Microsoft; USA). Statistical processing

of the results was performed by the analysis of variance with the Statistica 13.1 software package (StatSoft Inc.; USA). Statistical significance of the differences was analyzed using the Pearson’s χ² test. The differences were considered significant when p < 0.05.

RESULTS

Analysis of anthropometric traits in the studied group of children showed that the gradual increase in the height was observed both in boys and girls aged 12–16. In view of the fact that body weight is a dynamic parameter, depending primarily on the actual nutrition and the levels of physical activity, the analysis of dynamic changes in this trait has revealed no gradual increase with age and has reflected the correlation of the mean values with the percentage of children with the physical development disorders in the specified age group (Fig. 1).

Thus, when assessing physical development using the regional regression scores, it was found that more than 2/3 of the examined school students were constituted by children with the normal pattern of physical development, while the percentage of children, who’s body weight deviated from the reference values, was 30.44% in boys, and 38.36% in girls. However, the percentage of overweight children in boys and girls was the same (22.61% and 23.43%), and the proportion of overweight children was higher in the group of girls (14.93%), than in the group of boys (7.83%, p < 0.01).

Estimation of physical development based on the BAZ indices showed that in the studied group, children with normal body weight (70.2%) prevailed among both boys (147/230, 63.9%), and girls (157/201, 77.6%). Low body weight was found in seven children (1.6%) in the studied sample: four boys, and three girls. Excess body weight and obesity were revealed in less than one third of the surveyed children (in 19.1%, and 9.1%, respectively). Furthermore, there were no significant differences in the percentage of obese children among boys and girls (p = 0.207), while the proportion of overweight children was significantly higher in boys, than in girls (p < 0.01). Severe obesity (BAZ > +3.0) was found in three boys, and two girls (Table 2).

Comparison of the results, obtained by assessing physical development in accordance with the regional scores and the WHO standards (BAZ, Z-score), showed that Z-score revealed a significantly larger number of overweight and obese children among boys (p < 0.01). Regression scores revealed the insignificantly higher proportion of underweight boys (p = 0.285) and the significantly higher proportion of underweight girls (p < 0.01) (Fig. 2).

Based on the BIA data, a half of children in the studied sample had the excessive fat content. Furthermore, excess body weight was found in 42.2% of boys and 40.8% of girls, and obesity was found in 6.5% and 7.5%, respectively. Based on the %BF, 6.1% of boys and 3.5% were overweight. Thus, BIA of body composition in children revealed a normal body fat percentage, appropriate for age, gender, and anthropometric data, only in a half of the surveyed children, which made up 45.2% in the group of boys, and 48.3% in the group of girls (Fig. 3).

When assessing body fat percentage in children with various levels of physical development based on the regression scores, the following was found: in the group with normal physical development, the proportion of children with normal body fat percentage was 40%, while 44.7% of the surveyed individuals had excess fat content, and about 16.8% had low fat content. In the group of overweight children, high fat content values were found only in 72.7% of cases, which was indicative of the excess in other body weight characteristics (skeletal muscle mass, total body water, etc.) in 27.3% of children in this subgroup. The surveyed underweight children had a low body fat percentage in a half of cases (Fig. 4).

Studying the nutritional status in children with the relevant BAZ characteristics revealed 39.7% of surveyed individuals with normal body fat percentage; 21.9% of children had the low body fat percentage, and 38.2% of children had the excess body fat content. Among the surveyed children with BAZ between +1.0 and +2.0 Z-score (overweight), excess body fat percentage was revealed only in 56.1% of cases, 36.6% had a normal body fat content, and 7.3% had a low fat content. Obesity, defined based on BAZ, was confirmed by the %BF values in 16.7% of cases, and low body weight was confirmed in 71.4% of cases of the appropriate subgroup of the sample (Fig. 4).

Thus, body weight aberrations, diagnosed based on the regional scores, were confirmed by the data of BIA in the

significantly larger number of cases compared to the results of the assessment based on the BAZ indices (82/431, 19.7% and 61/431, 14.15%, \( p < 0.05 \)).

**DISCUSSION**

Our research, focused on studying the anthropometric indicators, involving the assessment of the school students aged 12–16 based on the regression scores, as well as on the calculated BAZ indices and %BF values, revealed numerous overweight and obese children. When using the anthropometric diagnosis methods, the most pronounced fluctuations of body weight, including the upward (excess weight) and downward (underweight) bias, were identified by assessment, involving the use of regression scores. It is interesting to note that when using the body fat percentage values obtained by BIA as a criterion of excess body weight instead of the results of estimation based on the regional standards and BMI, the proportion of children, who could be diagnosed with overweight and obesity, changed significantly.

No significant differences in the number of children with the normal pattern of physical development and children with body weight fluctuations between boys and girls were revealed based on the %BF values. Furthermore, BIA made it possible to reveal a large proportion of overweight and obese children among the individuals with the normal pattern of physical development (based on the regression scores and BAZ indices).

The period of development between 12–16 years of age is a critical period, when the risk of obesity increases by several times [7, 24]. Moreover, 60% of children with excess body weight in adolescence would be obese in adulthood, with the more severe course of obesity, prominent body weight increase and high prevalence of comorbidities, in contrast to the adult-onset obesity [7, 25]. That is why the early detection of premorbid conditions, aimed at adjusting the child’s diet and daily routine, is a crucial step in preventive medicine in terms of obesity prevention. According to our study, the results of which are in line with the results, obtained by other researchers [5, 6, 9], the anthropometric trait assessment results could be considered the most important criteria to be used in the routine check-ups, allowing one to refer the child to endocrinologist and nutritionist, and if necessary, for further treatment.

However, the findings showed that only 2/3 of the school students, diagnosed with overweight with the use of anthropometric techniques, had the excess body fat content. Nevertheless, body fat percentage was normal in one third of children in the surveyed sample, and no therapeutic interventions were required. Therefore the method of BIA, allowing one to detect changes not only in the body fat mass, but also in all the fat-free (lean) body mass components, could be considered the diagnostic method, allowing the specialists to start treatment, such as diet therapy, and to dynamically monitor the efficiency of the interventions.

Close practical links between the BIA of body composition and the anthropometric assessment of young patients were frequently discussed in scientific literature [19, 26, 27] with the emphasis on the high level of accountability of the biophysical method. Unfortunately, the diagnostic significance and the

---

**Fig. 2.** Comparison of the results of the physical development assessment with the use of regression scores and BAZ indices in the groups of boys and girls, constituting the studied sample

**Fig. 3.** Distribution of %BF in the groups of boys and girls, constituting the studied sample
criteria for the BIA results interpretation in combination with the anthropometric data have not been reflected in the federal guidelines on the diagnosis and treatment of obesity, which hampers the practical application of the method.

CONCLUSIONS

The study of anthropometric traits in the Samara school students aged 12–16 has revealed a significant proportion of children, having problems with physical development. The highest proportion of children with body weight fluctuations has been revealed by the assessment with the use of the regional age-based and gender-based regression scores, fitted with body weight as dependent variable and height. The analysis of body fat content in children with different levels of physical development has made it possible to identify the excess body fat percentage in children with the normal pattern of physical development (harmonious physical development). Thus, bioimpedance analysis of body composition in combination with the anthropometric data could be used as a reliable method for the diagnosis of the nutritional status disorders in children and adolescents.

CONSORTIUM AND RECONSOLIDATION OF VISUAL AND SEMANTIC MEMORY IN PARKINSON’S DISEASE

Nikishina VB1, Pettrash EA2, Shuteeva TV2, Zakharova IA1

1 Pirogov Russian National Research Medical University, Moscow, Russia
2 Kursk State Medical University, Kursk, Russia

Cognitive and mnestic impairments have a significant negative impact on the quality of parkinsonian patients’ life. Memory impairment causes changes in the mechanisms of information processing. The aim of this study was to investigate the characteristics of transformations undergone by memorized visual and semantic content during memory consolidation and reconsolidation in patients with Parkinson’s disease. The study was conducted on 32 male patients with PD (ICD code: G20). Among the patients, 9 had rigidity/bradykinesia-dominant PD, 11 had tremor-dominant PD, and 12 suffered from a mixed type of PD. Short-term memory span was assessed using the 10 words and the visual memory tests proposed by Luria. As stimuli materials we used a symbolic representation of the old Greek letter resembling an owl and a translated excerpt from a Canadian aboriginal epic. Regardless of the PD form, the quality of the memorized information was either altered or completely lost. The mechanisms underlying such transformations differed quantitatively depending on the PD form. Transformation of the memorized information occurred in the conditions of both incidental and deliberate memorization and was represented by distortions (substitution of the original content with contabulations) and simplifications of the structural and semantic organization. We consolidated significantly lesser amount of auditory verbal (p = 0.018) and visual (p = 0.029) information. This trend was consistent with the pronounced distortion of content during its retrieval.

Когнитивные и мнемические нарушения играют существенную роль в снижении качества жизни пациентов с болезнью Паркинсона (БП). Нарушения памяти приводят к изменению (трансформации) механизмов переработки информации. Целью работы было изучить особенности трансформации зрительно-образного и семантического содержания, подлежащего запоминанию, в процессах консолидации и реконсолидации у пациентов с БП. Объём выборки составил 32 пациента мужского пола с диагнозом G20 «Болезнь Паркинсона»: 12 пациентов со смешанной (акинетико-ригидно-дрожательной) формой, 9 пациентов с акинетико-ритидной формой и 11 пациентов с дрожательной формой болезни Паркинсона. Объём кратковременной памяти оценивали с помощью методик «10 слов» и «Зрительная память» А. Р. Лурия. Стимулирующий материал для экспериментального этапа исследования представлял собой символьное изображение буквы древнегреческого алфавита, напоминающего сову, а также текст из эпоса индейцев Канады на русском языке. Установлено, что вне зависимости от формы заболевания при БП фиксируется изменение качества запоминаемой информации либо ее полная потеря. Механизмы потери информации имеют качественные различия при разных формах заболевания. Трансформация сохраняемой информации в целенаправленном и при нецеленаправленном запоминании происходит либо в форме искажения (подмена исходного содержания конфабуляциями), либо в форме сокращения (упрощения структурно-семантической организации). Консолидируется значительно меньший объём информации как слухоречевой (р = 0.018), так и зрительно-образной (р = 0.029). Данная тенденция соотносится с выраженным искажением в процессе извлечения информации.

Ключевые слова: зрительно-образная память, семантическая память, целенаправленное запоминание, нецеленаправленное запоминание, консолидация, реконсолидация, болезнь Паркинсона

BULLETIN OF RSMU | 6, 2021 | VESTNIKRGMU.RU
Parkinson’s disease (PD) is an age-related progressive neurodegenerative disorder characterized by high rates of disability and poor prognosis. Being the second most common neurodegenerative disorder, PD poses a serious challenge to healthcare and society.

The diversity of clinical manifestations of PD is linked to the death of dopaminergic neurons in the striopallidary system. In addition to motor symptoms, which are highly common in parkinsonian patients, PD has varied non-motor manifestations, including autonomic and sensory dysfunction, pain, affective disorders, and cognitive impairment. The diversity of symptoms and the high rate of cognitive impairment diminish the quality of life of parkinsonian patients and their families and are the focus of clinical attention.

In all its diversity of forms and processes, memory has adaptive potential that maintains the quality of life in parkinsonian patients.

Studies of cognitive and, more specifically, mnestic functions in PD patients have been implemented by Russian [1] and foreign [2–21] researchers.

Parkinsonian patients are reported to suffer a significantly declining quality of life [2]. No association has been found between the cognitive status of PD patients on the MMSE scale and attention/memory deficit experienced by the patients.

PD is characterized by a long preclinical stage lasting up to 20–30 years. The clinical manifestations of the disease appear when degeneration of substantia nigra neurons and striatal axons reaches 50–60% and 70–80%, respectively [11]. In addition to dopaminergic neurons in the striata nigra, dopaminergic neurons in other brain regions, including the tuberoinfundibular system, are affected. Disruption of the dopaminergic pathway in the striatum critically affects the continuous process of working memory updating [7]. Neurodegeneration begins in the dorsal vagal and the anterior olfactory nuclei and then spreads sequentially to the locus coeruleus, substantia nigra and basal regions of the anterior brain; it is only in the advanced stages of the disease that neurodegeneration hits the neocortex, especially the limbic and the multimodal association cortices of the frontal and temporal lobes [18].

The underlying mechanism of PD involves intraneuronal aggregation of pathological alfa-synuclein, the primary component of Lewy bodies. In neurodegenerative disorders, chronic activation of the microglia and astrocytes results in reactive microgliosis and astrogliosis. In PD, oligodendrocytes are also involved, which suggests that PD affects signal transmission in the brain. Gliosis caused by neurodegeneration blocks transmission of nerve impulses and impedes formation of new neuronal connections, which form the morphological and functional basis of memory consolidation and reconsolidation. Impairment of temporal processing is associated with neuronal apoptosis, which hampers information transfer from short-term to long-term memory and back [6]. In addition to the overall visuospatial dysfunction, patients with PD have verbal memory impairment. A direct association has been established between the duration of the disease and visuospatial short-term memory impairment [13].

The methodology of our research into consolidation and reconsolidation of visual and semantic information in parkinsonian patients is premised on the concept of working memory developed by Velichkovsky BB (2015). Working memory (WM) is a system of cognitive processes that enable temporary information storage and processing. Being structurally heterogeneous, WM consists of multiple components for temporary information storage and processing that have various functional characteristics; WM also includes a system of functional mechanisms. [20, 21]. WM is not stimulus-specific, and its content is determined by the type of memory involved in input processing. Based on the functional outcome, memory can be classified into nonverbal (visual, symbolic and auditory) and semantic. Based on the type of regulation, memorization can be classified into deliberate (intentional) and incidental (unintentional).

Regardless of whether memorization is deliberate or incidental, incoming information is simplified (compressed) at the encoding stage. During processing, information is converted into a primary mnestic image or primary semantic content. In WM, storage is implemented by means of short-term and long-term storage mechanisms. Short-term storage mechanisms are used for temporary storage of information essential for solving a current cognitive task [1, 2].

Fig. 1 shows schematic representation of consolidation and reconsolidation of visual and semantic information.

During memory consolidation, short-term memories are converted into long-term memories, and the retained information, be it visual or semantic, undergoes further transformations in accordance with the previous experience. Freshly learned experiences are compared to “old” information stored in the long-term memory. Long-term memory harbors information that can be re-activated to solve a current

![Fig. 1. Schematic representation of consolidation and reconsolidation of visual and semantic information](image-url)
task. Consolidated memories are retrieved (i.e. undergo reconsolidation) from long-term memory, which comprises a system of images, symbols, signs, and a semantic system organized into a coherent experience. Both visual and semantic information learned in the previous experience undergoes reconsolidation and is transformed in accordance with fixed object-significant identification characteristics.

Any WM impairment reduces human capacity to process information or make an optimal decision and lessens the overall adaptive potential [1, 2].

The aim of this study was to investigate the characteristics of visual and semantic content transformation during memory consolidation and reconsolidation in patients with PD. We hypothesize that information acquired through either deliberate or incidental memorization by such patients is distorted or completely lost in the absence of pronounced cognitive dysfunction and regardless of the PD form (rigidity/bradykinesia-dominant, tremor-dominant or mixed).

METHODS

A total of 32 male patients diagnosed with Parkinson’s disease (ICD disease code: G20) were enrolled in the study. Clinical manifestations assessed on the Hoehn and Yahr scale were consistent with stage 2 of the disease at the time of this study. The participants were stratified into 3 groups by the form of the disease: group 1 (n = 12) included patients with mixed PD, group 2 (n = 9) comprised patients with rigidity/bradykinesia-dominant PD, and group 3 consisted of patients with tremor-dominant PD (n = 11). Inclusion criteria: age of 60–65 years (mean age: 62.4 ± 2.1 years), duration of PD no more than 3 years (mean duration: 2.2 ± 0.57 years), absence of cognitive disorders (MMSE score: at least 24 points). All patients were receiving levodopa therapy at baseline (average dose: 594.2 ± 236.2 mg a day).

Exclusion criteria: severe chronic disorders, TB, viral hepatitis, HIV, and other recurrent infections.

The study was conducted in 3 stages. In the first stage, the patients underwent a physical and neurological examination.

In the second stage, the storage capacity of explicit (intentional) short-term visual and auditory verbal memory was assessed. The span of auditory verbal memory was assessed using a Luria memory words test. Briefly, the patient was read a list of 10 semantically unrelated monosemantic one- and two-syllable words denoting concrete objects and was asked to recall the words immediately after presentation. The procedure was repeated 5 times. The following parameters were recorded: the number of correctly recalled words, the number of repeated words during each recall round, and the number of words that were not on the list. Short-term visual memory span was assessed using a Luria visual memory method. Briefly, the patient was shown a table of 16 cells; each cell contained an outline drawing of an object (a geometric shape or an item). The patient was given 2 min to look at the images. Then, the patient was asked to name the objects they were able to memorize. The procedure was repeated 5 times. The following parameters were recorded: the number of correctly reproduced visual stimuli, the number of repeated objects during each recall round, and the number of new words that were not present in the original table.

In the third stage, we empirically studied consolidation and reconsolidation of explicit and implicit visual and semantic memory types in patients with PD. The methodology for this stage was adopted from Bartlett’s experiment on memory reconstruction during its active retrieval. Each patient was instructed about the experiment individually.

During the experiment, the patient was presented with a visual stimulus — a symbolic drawing shown in Fig.2. This particular stimulus was reliably unfamiliar to the patients, hence its choice. The drawing was a letter from the old Greek alphabet that resembled an owl. The symbolic drawing (symbol) had 4 parts: a head, a body, a wing and a leg. Each of these parts consisted of smaller elements, e.g. the head consisted of 2 elements: the head itself and a tick, etc.

The stimulus material for the study of semantic memory was a Russian translation of an excerpt from a Canadian aboriginal epic. The excerpt contained 79 units of meaning (33 sentences, 295 words, a total of 1,427 characters). The units of meaning were defined as grammatical forms charged with semantic content and implemented in different combinations of nouns (the central lexical units of the language) with other forms (adjectives, verbs, pronouns). Semantic memory was assessed using the following parameters: the number of correctly reproduced sentences, the number of correctly reproduced semantic units, the number of incorrectly reproduced sentences, the number of semantic errors, the number of errors in the order of sentences, the number of errors in the order of semantic units. The data were collected into a specially designed semantic card.

For immediate reproduction of the presented stimulus material, the patients were instructed to draw a copy of the original visual stimulus. Next, the patients were asked to retell the Indian story immediately after hearing it. Reproduction ensured that information was retained. Then, the patients were asked to draw the presented visual stimulus from memory and to retell the text 40 min, 4 h and 36 h after the initial presentation.

Statistical analysis was conducted using descriptive (means and standard deviations) and comparative (the nonparametric Mann–Whitney U and Wilcoxon sign-ranked tests) statistics. Absolute values were analyzed.

RESULTS

The experiment revealed that the span of short-term visual and auditory verbal memory was reduced in parkinsonian patients regardless of the PD form. The graphic representation of the results in Fig. 3 reflects the number of reliably correct responses following presentation of the verbal stimuli.

The comparative analysis of short-term auditory verbal and visual memory aided by the non-parametric paired Mann–
Errors made by the patients with bradykinesia-dominant PD were mostly perseverative reproduction of the actual visual and auditory verbal stimuli without confabulation (addition of new information, false memories). The patients with the mixed form of PD made a lot of confabulation errors, i.e. repeatedly reported words and objects that were absent in the initial presentations. The proportion of such additions was as high as 51.18 ± 6.34%. About half of the reported visual and verbal stimuli were additions semantically unrelated to the presented stimulus material. The proportion of confabulation errors made by the patients with tremor-dominant PD was also significant (34.44 ± 5.12%). However, unlike patients with mixed PD, the additions made by this group of patients when reporting the auditory verbal stimuli were mostly verbs semantically unrelated to the presented verbal stimuli. Responses to the presented visual stimuli were word combinations of two types: noun + adjective and noun + verb. The patients with tremor-dominant PD demonstrated these response types when reproducing the presented and false stimuli.

These findings suggest that, regardless of the PD type, both visual and auditory verbal information underwent a transformation (was altered) at the stage of deliberate memorization during the presentation of the stimuli. With every subsequent presentation and reproduction of the stimuli, the patients did not correct the errors, but instead persisted in reproducing false memories, or confabulations. This suggests consolidation of false memories by means of their transfer to the long-term memory storage.

In the next stage, incidental memorization was studied by studying consolidation and reconsolidation of visual and semantic memory. We discovered that the semantic content of verbal information was completely lost during incidental memorization by patients with PD. The semantic information was altered at the stage of its encoding during immediate reproduction of the heard text. In total, 23–28% of the semantic content was missing. During story retelling, a significant proportion of semantic units was lost. The proportion of the omitted semantic units increased to 50–53% after a 40-minute delay. Four hours after the initial presentation, the patients with any form of PD were able to reproduce only 1/4 of the story’s semantic content (21–23%).

The loss of the original semantic content was accompanied by the simplification of linguistic and semantic structures: the patients used syntactically simple sentences and named only objects and actions. Some sentences were merely object descriptions; structurally, they were a combination of a noun and an adjective. Story retelling was reduced to the description of objects and their actions; causal relationships were totally missing. Regardless of the PD form, a complete loss of the semantic content was demonstrated by all the patients after a 36-hour delay. Substitutions were the most prevalent type of error: the patients named the objects, described their characteristics and actions but did not make causal connections. And even with substitutions, there was a 3-fold reduction in the qualitative and quantitative structure of the text: the retold story contained 81 words and 23 semantic units vs 295 words and 79 semantic units in the original text. This reduction occurred regardless of the PD form. The retold story was lexically and syntactically simplistic and was unrelated to the original text. These findings suggest inhibition of verbal information in patients with PD.

While retelling the story immediately after its presentation, patients with rigidity/bradykinesia-dominant PD cut down the original story considerably but preserved its gist. There were almost no alterations during immediate recall. The participants with tremor-dominant PD reproduced the original semantic content overall correctly but still abridged it and made some insertions. This group of patients created causal links between the newly introduced and the initially present objects. The participants with tremor-dominant PD uttered short simple sentences consisting of 4 words at best, with preserved semantic content. The patients with mixed PD incorrectly reproduced a few semantic units during immediate recall (24 correct semantic units vs 79 units in the original text) but preserved the main idea. Similar to the patients with tremor-dominant PD, the patients with mixed PD simplified language structures while retelling the story, using unexpanded sentences, which obfuscated its understanding.

Story retelling 40 minutes after its initial presentation revealed further loss of the semantic content regardless of the PD form. In the stories retold by the patients with mixed PD, only 6 sentences were consistent with the initial text in terms of semantic content. Other semantic units, which were mostly descriptions of objects and actions, were altered or substituted. The patients with rigidity/bradykinesia-
Men liked seals, big and beautiful animals. They were resting on the shore, basking in the sun as follows: the patients in other semantic fields. For example, the initial confabulations (semantic units containing information about only 5 of 79 semantic units contained in the original text).

The patients with tremor-dominant PD correctly reproduced most prevalent errors made by the patients with mixed PD. The number of causal relationships ranged from 1–2 sentences. The semantic content was altered or substituted.

After a 36-hour delay, the patients with any form of PD were able to reproduce 22–25% of the original semantic content. Their stories were dominated by object and action naming. The objects mentioned in the initial text were substituted. The story was retold in short kernel sentences (subject + predicate). The sentences were ungrammatical and lacked agreement. A tendency to perseveration was observed in the patients with mixed and rigidity/bradykinesia-dominant PD: sentences were repeated up to 4 times. The causal relationships were totally missing.

After a 36-hour delay, the total loss of the original semantic content was demonstrated by all the patients regardless of the PD form. The number of causal relationships ranged from 1 to 4. The number of insertions (new objects) varied from 5 to 7, which was comparable with the number of objects in the presentation (Fig. 4).

A tendency to perseveration was observed in the patients with rigidity/bradykinesia-dominant PD after a 4-hour delay, the patients with any form of PD were able to reproduce 22–25% of the original semantic content. Their stories were dominated by object and action naming. The objects mentioned in the initial text were substituted. The story was retold in short kernel sentences (subject + predicate). The sentences were ungrammatical and lacked agreement. A tendency to perseveration was observed in the patients with mixed and rigidity/bradykinesia-dominant PD: sentences were repeated up to 4 times. The causal relationships were totally missing.

After a 36-hour delay, the total loss of the original semantic content was demonstrated by all the patients regardless of the PD form. The number of causal relationships ranged from 1 to 4. The number of insertions (new objects) varied from 5 to 7, which was comparable with the number of objects in the presentation (Fig. 4).

A tendency to perseveration was observed in the patients with rigidity/bradykinesia-dominant PD after a 4-hour delay, the patients with any form of PD were able to reproduce 22–25% of the original semantic content. Their stories were dominated by object and action naming. The objects mentioned in the initial text were substituted. The story was retold in short kernel sentences (subject + predicate). The sentences were ungrammatical and lacked agreement. A tendency to perseveration was observed in the patients with mixed and rigidity/bradykinesia-dominant PD: sentences were repeated up to 4 times. The causal relationships were totally missing.

After a 36-hour delay, the total loss of the original semantic content was demonstrated by all the patients regardless of the PD form. The number of causal relationships ranged from 1 to 4. The number of insertions (new objects) varied from 5 to 7, which was comparable with the number of objects in the presentation (Fig. 4).

After a 36-hour delay, the total loss of the original semantic content was demonstrated by all the patients regardless of the PD form. The number of causal relationships ranged from 1 to 4. The number of insertions (new objects) varied from 5 to 7, which was comparable with the number of objects in the presentation (Fig. 4).

After a 36-hour delay, the patients with rigidity/bradykinesia-dominant PD were able to reproduce 18 semantic units, of them 6 were consistent with the initial semantic content of the presented text, 4 units were confabulations (the patients introduced new objects, object characteristics or causal relationships). The overwhelming majority of semantic units in the retold story were perseverative, i.e. repeated multiple times in different parts of the retold text. Perseverative confabulations (falsely reproduced semantic units absent in the initial text) were the most prevalent errors made by the patients with mixed PD.

After a 4-hour delay, the patients with rigidity/bradykinesia-dominant PD were able to reproduce 18 semantic units, of them 6 were consistent with the initial semantic content of the presented text, 4 units were confabulations (the patients introduced new objects, object characteristics or causal relationships). The overwhelming majority of semantic units in the retold story were perseverative, i.e. repeated multiple times in different parts of the retold text. Perseverative confabulations (falsely reproduced semantic units absent in the initial text) were the most prevalent errors made by the patients with mixed PD. The patients with tremor-dominant PD correctly reproduced only 5 of 79 semantic units contained in the original text. Confabulations (semantic units containing information about objects and their actions from the initial text) were used by the patients in other semantic fields. For example, the initial text contained a sentence about seal hunting: One night two young men from Egulac went down to the river to hunt seals. The retold story did not contain information about seal hunting. The sentence reproduced by the patient was as follows: Men liked seals, big and beautiful animals. They were resting on the shore, basking in the sun. This example demonstrates that the semantic content of the reproduced statement deviated from the original sentence; information about seals was semantically misrepresented.

The following patterns were detected while studying visual memory consolidation and reconsolidation (Fig. 5).

Regardless of the PD form (tremor-dominant, rigidity/bradykinesia-dominant, mixed), the patients transformed the presented symbolic drawing into a non-abstract image at the stage of visual information retrieval. When the patients were drawing a copy of the presented symbolic picture (i.e. the stage of encoding, or, in other words, reproduction of the symbol from the template), they tended to transform the symbol into a non-abstract image (bird, owl). This tendency intensified with every subsequent reproduction. The original content was altered, simplified or totally lost. The number of major elements present in the original drawing and the accuracy of their reproduction (number of smaller elements, their arrangement in the picture, including relative to each other, the shape and size of elements) decreased; new elements absent in the original drawing were introduced to the composition.

At the stage of incidental memorization of the presented drawing, the latter underwent transformation from being symbolic to becoming descriptive. This resulted in memorizing the altered image.

All the patients with rigidity/bradykinesia-dominant PD altered the presented visual stimulus only slightly during copying. The number of details, their shapes and inter-element arrangement were reproduced correctly. The patients with tremor-dominant PD omitted some elements of the original drawing and altered their size but preserved the general layout. The patients with mixed PD reproduced a very altered silhouette; the details were also very different from the original drawing.

After a 40-minute delay, further alteration of the memorized, now non-abstract image of a bird (an owl) was observed, mostly in the number of the details. Regardless of the PD form, the drawing looked simplified: its parts were distorted and the elements were few. There were new additions positioned predominantly in the bottom of the drawing. Introduction of new elements to the drawing was accompanied by the omission of the original elements. The patients with rigidity/bradykinesia-dominant PD added partially or completely overlapping lines. The patients with tremor-dominant PD simplified the elements and their initial arrangement. Because some lines in the drawing partially overlapped, this created a variety of new elements initially
After a 4-hour delay, we observed a transformation of the memory image (its reconstruction, in Bartlett’s terms) characterized by the loss of the initial elements: several elements were fused into one (tremor-dominant PD) and new elements were introduced (rigidity/bradykinesia-dominant and mixed PD). Regardless of the PD form, the patients tended to simplify the image by reducing the number of parts initially present in the drawing and adding new lines that significantly enhanced the contours of the elements. Superimposition of new elements not found in the original drawing was typical for the patients with mixed PD.

After a 36-h delay, the shape of the initial symbol was completely distorted: the number of parts was reduced to one (the contour of the figure in the drawing) or 2.

Pairwise comparison revealed no significant differences between the groups of patients with different PD forms in the number of correctly reproduced semantic units during the text recall task and the number of correctly reproduced details of the symbolic drawing after a 36-hour delay following incidental memorization (Fig. 6).

The statistical analysis of significance of differences uncovered the following trends. Regardless of the PD form, the patients demonstrated a complete loss of the visual and semantic content in the absence of cognitive impairment. This indicates impairment of consolidation and reconsolidation of memory traces in PD. The trend may be explained by the fact that at the stage of encoding (copying the symbol from the presented visual template and then during immediate recall

Fig. 5. Drawings made by the patients with different PD forms in the immediate recall test and after a 40-minute, 4-hour and 36-hour delay.
An attempt to identify PD-specific tests demonstrate that patients with PD have recall rather than memory for routine activities in patients with PD [5]. Memory short-term memory impairments, attention deficit, and poor consistent with the reports of other researchers describing reduced in the patients with any PD form. This finding was

DISCUSSION

Regardless of the PD form, short-term memory span was reduced in all the patients. The errors made by the patients depended on the form of the disease.

Differences observed between the groups during immediate recall and after 40-minute, 4-hour and 36-hour delays suggest that each form of PD is characterized by a specific type of information transformation. A significant amount of information, be it visual or semantic, is lost in rigidity/bradykinesia-dominant PD. Information is simplified and the resultant gaps are filled with perseverative simplified structures. Patients with mixed PD alter the content by introducing confabulations and also by perseveration. Similar to patients with mixed PD, patients with tremor-dominant PD distort information at the stage of encoding by introducing confabulations semantically close to the presented stimulus. This trend detected during the study of consolidation and reconsolidation of visual and semantic memory is corroborated by the results of research into the morphofunctional level through creation of new neuronal connections. Optimization of mnestic processes of consolidation and reconsolidation of visual and semantic information regardless of PD type and, therefore, involvement of cortical and subcortical brain structures into the process at the morphofunctional level through creation of new neuronal connections. Optimization of mnestic processes of consolidation and reconsolidation will in turn increase the compensatory and adaptive potential, as well as the quality of life of patients with PD.

CONCLUSIONS

Mnestic changes due to the pathological processes associated with PD affect the qualitative and quantitative characteristics of memory consolidation and reconsolidation, including accuracy and memory span, regardless of the disease form (rigidity/bradykinesia-dominant, tremor-dominant or mixed) or result in the lack of presentation of the reconsolidated content during recall. Alterations depend on the type of the disease: elements fusion is typical for tremor-dominant PD, addition of new elements is observed in tremor-dominant and rigidity/bradykinesia-dominant PD, whereas the superimposition of new elements absent in the presented visual stimulus occurs in mixed PD. Transformations of consolidated and reconsolidated information during incidental and deliberate memorization were represented by substitution (confabulation) of the original content and reduction (simplification of the structural and semantic structure of content organization). The patients were able to consolidate only a smaller amount of visual and auditory verbal information. With every recall, memory is reconstructed and its content is recategorized. Reconsolidation always follows recategorization. This trend is consistent with pronounced distortion of information during reconsolidation.

Considering the need for improving the quality of life of parkinsonian patients, mnemotechnics should be included in the programs of social adaptation. Mnemotechnics will facilitate consolidation and reconsolidation of visual and semantic information regardless of PD type and, therefore, involvement of cortical and subcortical brain structures into the process at the morphofunctional level through creation of new neuronal connections. Optimization of mnestic processes of consolidation and reconsolidation will in turn increase the compensatory and adaptive potential, as well as the quality of life of patients with PD.

FACTORS ASSOCIATED WITH INCREASE IN ALCOHOL CONSUMPTION DURING FIRST MONTHS OF COVID-19 PANDEMIC AMONG ONLINE SOCIAL MEDIA USERS IN RUSSIA

Gil AU, Demin AK

The significant proportion of the Russian population are active online social media users. Changes in alcohol consumption in this target group during the COVID-19 pandemic remain understudied. The aim of this survey was to investigate changes in alcohol consumption and factors associated with the increase in alcohol use among online social media users in Russia during the first months of the COVID-19 pandemic. An online survey was conducted among 1,518 users of online social networking services popular in Russia from June to September 2020. The survey revealed that 35.4% of men and 25.6% of women started drinking more frequently during the first months of the pandemic; 24.9% of men and 17.7% of women increased their usual consumption (volume) of alcohol on a typical drinking occasion, whereas 28.5% of men and 27.9% of women increased the frequency of heavy episodic drinking. Adjusted binary logistic regression analysis revealed a positive association between the increase in the frequency of alcohol consumption and the following factors: age from 18 to 29 years (OR: 1.710; 95% CI: 1.002–2.917), severe restrictions in everyday private life (OR: 3.127; 95% CI: 1.011–9.675) and severe negative professional or financial consequences due to the spread of SARS-CoV-2 (OR: 2.247; 95% CI: 1.131–4.465). The odds of an increase in the frequency of heavy episodic drinking were more than twice higher (OR: 2.329; 95% CI: 1.001–5.428) among those who had experienced severe negative consequences of the pandemic to their professional and financial situation. Higher typical frequency and usual consumption (volume) of alcohol on a typical drinking occasion and higher typical frequency of heavy episodic drinking before the pandemic were positively significantly associated with the increase in these parameters of alcohol consumption during the first months of the pandemic. In times of large-scale epidemics and public health crises, it is advisable to consider the possibility of implementing screening and brief interventions, including via online social media, to prevent problems associated with alcohol use.

Keywords: alcohol, COVID-19, coronavirus, pandemic, social media, Facebook, VKontakte, Odnoklassniki, Twitter, Russia

Author contributions: Gil AU planned the study, designed the electronic questionnaire form, collected date, performed statistical analysis, interpreted the results and wrote the manuscript; Demin AK interpreted the results and wrote the manuscript.

Acknowledgements: The authors thank Uri and Raisa Gil for their help in disseminating information about the survey in online social media, for their critical comments on the interpretation and discussion of the results.

Значительная часть населения активно пользуется социальными онлайн-сетями, однако изменения потребления алкоголя в этой целевой группе в период пандемии COVID-19 малоизучены. Целью исследования было оценить изменения потребления алкоголя и факторов, связанных с ростом его потребления, в первые месяцы пандемии COVID-19 среди пользователей социальных онлайн-сетей в России. В период с июня по сентябрь 2020 г. 1518 пользователей наиболее популярных в России социальных онлайн-сетей прошли опрос в отношении изменений потребления алкоголя в первые месяцы пандемии COVID-19. Выявлена, что в первые месяцы пандемии 35,4% мужчин и 25,6% женщин увеличили частоту употребления алкоголя; 24,9% мужчин и 17,7% женщин увеличили разовый объем потребления алкоголя, а 28,5% мужчин и 27,9% женщин увеличили частоту случаев эпизодического употребления алкоголя в больших разовых количествах. На многофакторном уровне возраст 18–29 лет оказалось положительным фактором связи с ростом потребления алкоголя (ОР = 1.710; 95% ДИ = 1.002–2.917), очень сильные ограничения в повседневной жизни (3.127; 1.011–9.675) и очень сильные негативные последствия в отношении профессиональной или финансовой ситуации в связи с распространением SARS-CoV-2 (2.247; 1.131–4.465) были положительно взаимосвязаны с ростом частоты потребления алкоголя. Шансы увеличения частоты эпизодического употребления алкоголя в больших разовых количествах были более чем в два раза выше (2.329; 1.001–5.428) среди лиц, испытывших очень сильные негативные последствия в отношении профессиональной или финансовой ситуации. Более высокие привычные частоты употребления алкоголя, разовый объем употребляемого алкоголя и частота эпизодического употребления алкоголя в больших разовых количествах до пандемии были положительно статистически связаны с ростом этих параметров потребления алкоголя в первые месяцы пандемии.

Decision action taken to counter COVID-19 in Russia and worldwide during the first months of the pandemic slowed the spread of SARS-CoV-2 infection, but it also had a significant impact on many other aspects of life. During the nationwide Russian lockdown, implemented in the second quarter of 2020, the official unemployment rate grew by 2.1%, reaching 6.4%, and the real disposable income of the population fell by 8.4% in comparison with the same period in 2019 [1]. Income reduction and complete loss of income were reported by 61% and 13.5% of the population, respectively; 9.8% of the Russian population lost their jobs [2]. According to recent studies investigating the impact of COVID-19 restrictions across countries, the rates of depression, anxiety and stress among some population groups, especially among women, young adults and people with chronic diseases, have increased [3, 4]. In times of crisis, some turn to alcohol to cope with psychoemotional stress; this can heighten the risk of adverse short-term and long-term health effects and negative social consequences [5, 6]. Increased substance use following large-scale disasters is often the sign of people adopting a self-medicating strategy to deal with emotional distress [7–9]. Research warns that the COVID-19 pandemic may lead to a medium- and long-term increase in alcohol consumption, especially among men [10]. Early studies into the effects of the pandemic have discovered an association between poor overall mental health and increased alcohol use [11]. According to a study conducted in Canada, stress was the third most common (44%) cause of drinking during the pandemic. In the USA, psychological distress caused by the pandemic was associated with increased frequency of alcohol use in both men and women [12]. Research demonstrates that while some proportion of the adult population are increasing their alcohol consumption during the pandemic, an equal proportion are cutting down on alcohol, and 50–70% of the population are not changing their level of alcohol consumption [11, 13]. Because changes in alcohol consumption during the current pandemic may have serious long-term social and economic implications for individuals, groups of people and society as a whole [14, 15], there is a need to monitor these changes and analyze the contributing factors that come forward during a large-scale crisis.

In Russia, online social networking services are actively used by the significant proportion of the population. This opens up a possibility to rapidly assess alcohol consumption among Russian residents and remotely (i.e., via the Internet) implement brief interventions aimed at preventing health problems and other adverse outcomes associated with alcohol use. The aim of this study was to assess changes in alcohol consumption and the factors associated with the increase in alcohol use in the first months of the COVID-19 pandemic among online social media users in Russia in order to explore the possibility of delivering screening and preventive interventions, including those implemented via the Internet, aimed at identifying and preventing alcohol-related problems during large-scale epidemics and public health crises.

METHODS

An anonymous online survey was conducted from June 18 to September 30, 2020 among users of online social media popular in Russia (Odnoklassniki, VKontakte, Facebook and Twitter). The following inclusion criteria were applied: age ≥ 18 years, being an Internet user with or without a user account in the online social media mentioned above, informed consent to participate in the anonymous confidential online survey. Non-inclusion criteria: permanent residence of the respondent outside Russia. Exclusion criteria: refusal to participate or have one’s personal data processed at any stage of the study, inconsistent contradictory answers to the questions included in the survey. Any participant could refuse to participate at any stage of the study. The link to the survey was posted in the online social media in various groups, on popular pages and in the news feed. The survey was adapted from the pan-European study of alcohol use during the COVID-19 pandemic [10] and modified to assess alcohol consumption behaviors in the 3 months preceding the survey. A few original questions were added to the questionnaire to assess consumption of unrecorded alcohol, such as the homemade alcohol (samogon, homemade wine, braga), alcohol brought from abroad, falsified and counterfeit alcoholic beverages, alcohol-containing liquids not intended for drinking, and other types of unrecorded alcohol. Changes in alcohol use during the first months of the pandemic were assessed from changes in the amount and frequency of alcohol consumption and the frequency of heavy episodic drinking defined as 6 or more drinks or 60g of pure ethanol on a single occasion. Statistical analysis included calculation of descriptive statistics and estimation of the proportion of respondents stratified by sociodemographic or other characteristics who had reduced or increased the frequency of drinking or the amount of alcohol consumed. We also assessed associations between the increase in drinking frequency/amount of consumed alcohol during the first months of the pandemic (dependent variables) and the sociodemographic factors, typical frequency of drinking, the typical amount of consumed alcohol, and the typical frequency of heavy episodic drinking in the past 12 months preceding the pandemic, the perceived strength of COVID-19-associated restrictions in public and everyday private life, stress, negative impact of the pandemic on professional and financial situation, and other adverse consequences of the pandemic (independent variables). The presence, direction, strength and statistical significance of the associations were assessed using unadjusted and adjusted binary logistic regression analysis. Odds ratios (OR) and 95% confidence intervals (95% CI) were calculated as measures of association.

RESULTS

Of 1,518 respondents, 57.9% were women and 42.1% were men. The majority of the respondents (87.1%) had had an alcoholic drink at least once in 12 months preceding the study (Table 1). Over half of the respondents (55.9%) were 30–49 years old and almost two-thirds had attended and/or completed higher education (63.8%). More men than women lived in larger settlements (p = 0.010) and higher-income households (p < 0.001). During the first months of the pandemic, their income had changed or fallen less often than that of women (p = 0.014). The usual frequency of drinking, the number of standard drinks consumed on a typical occasion, the frequency of heavy episodic drinking, and the proportion of persons consuming unrecorded alcohol were higher among men than among women (p < 0.001). Overall, the male respondents reported they had encountered restrictions in public (p = 0.007) and everyday private (p = 0.003) life less often than women. However, almost a quarter of men (23.2%) and a third of women (30.8%) said they had encountered severe restrictions in public life, whereas one-fifth of men (19.9%) and a quarter of women (25.4%) reported having faced severe restrictions in their everyday private life during the first months of the pandemic. Men had experienced the negative effects of the pandemic on their professional or financial situation significantly less frequently than women (p = 0.005). Only 30.4% of men and 23.5% of women reported they had experienced no negative effects on their professional or financial situation. The pandemic
was a source of stress for 50.4% of men and 69.5% of women ($p < 0.001$). A history of confirmed SARS-CoV-2 infection in a respondent, their family or close friends was reported by 21.9% of the participants, with no significant differences by sex (Table 1). In the first months of the pandemic, 35.4% of men and 25.6% of women had used alcohol more frequently than before the pandemic; 24.9% of men and 17.7% of women had increased usual consumption (volume) of alcohol on a typical drinking occasion; the frequency of heavy episodic drinking had increased in 28.5% of men and 27.9% of women.

Results of unadjusted and adjusted logistic regression analysis are shown in Tables 2–4.

Factors associated with the increase in the frequency of alcohol consumption during the first months of the pandemic

After adjustment for confounders, positive statistically significant associations between the increase in the frequency of alcohol consumption during the first months of the pandemic and the following factors were identified: age of 18–29 years (OR: 1.710; 95% CI: 1.002–2.917), higher typical frequency of alcohol use before the pandemic (from OR: 3.190, 95% CI: 1.887–5.392 for consumption 2–4 times a month, to OR: 18.727, 95% CI: 9.639–36.383 for consumption more than 2–3 times a month), higher usual consumption (volume) of alcohol on a typical drinking occasion before the pandemic (from OR: 1.941, 95% CI: 1.244–3.029 to OR: 2.234, 95% CI: 1.180–4.233), heavy episodic drinking with a frequency of once a month (OR: 2.012; 95% CI: 1.081–3.746), and severe negative consequences of the pandemic to the professional or financial situation (OR: 2.247; 95% CI: 1.131–4.465, Table 2).

Factors associated with the increase of the usual consumption (volume) of alcohol on a typical drinking occasion during the first months of the pandemic

Positive statistically significant associations were identified between the increase of the usual consumption (volume) of alcohol on a typical drinking occasion and the following factors: age of 18–29 years (OR: 1.710; 95% CI: 1.002–2.917), higher typical frequency of alcohol use before the pandemic (from OR: 3.190, 95% CI: 1.887–5.392 for consumption 2–4 times a month, to OR: 18.727, 95% CI: 9.639–36.383 for consumption more than 2–3 times a month), higher usual consumption (volume) of alcohol on a typical drinking occasion before the pandemic (from OR: 1.941, 95% CI: 1.244–3.029 to OR: 2.234, 95% CI: 1.180–4.233), heavy episodic drinking with a frequency of once a month (OR: 2.012; 95% CI: 1.081–3.746), and severe negative consequences of the pandemic to the professional or financial situation (OR: 2.247; 95% CI: 1.131–4.465, Table 2).

Reported encountering COVID-19-related restrictions in public life in the past 3 months

| No restrictions                               | 17/87 | 19.5 | 1.0 | 1.0 |
| Slight restrictions                           | 84/407 | 20.6 | 1.071 (0.598–1.916) | 0.703 (0.320–1.977) |
| Moderate restrictions                         | 133/413 | 32.2 | 1.956 (1.108–3.454) | 1.068 (0.349–3.270) |
| Severe restrictions                           | 151/363 | 41.6 | 2.933 (1.659–5.184) | 1.020 (0.315–3.299) |

Reported encountering COVID-19-related restrictions in their everyday private life in the past 3 months

| No restrictions                               | 18/111 | 16.2 | 1.0 | 1.0 |
| Slight restrictions                           | 101/470 | 21.5 | 1.414 (0.815–2.453) | 1.636 (0.622–4.304) |
| Moderate restrictions                         | 133/385 | 34.5 | 2.727 (1.579–4.711) | 2.594 (0.890–7.564) |
| Severe restrictions                           | 134/304 | 44.1 | 4.073 (2.342–7.081) | 3.127 (1.011–9.675) |

Reported negative consequences of the pandemic to their professional or financial situation in the past 3 months

| No negative consequences                      | 65/318 | 20.4 | 1.0 | 1.0 |
| Slight negative consequences                 | 142/492 | 28.9 | 1.579 (1.129–2.208) | 1.240 (0.772–1.990) |
| Moderate negative consequences               | 87/239 | 36.4 | 2.228 (1.525–3.255) | 1.524 (0.848–2.739) |
| Severe negative consequences                 | 89/211 | 42.2 | 2.839 (1.930–4.177) | 2.247 (1.131–4.465) |

Reported confirmed SARS-CoV-2 infection in themselves, their family or close friends in the past 3 months

| Yes                                           | 82/278 | 29.5 | 0.956 (0.714–1.280) | 0.846 (0.575–1.245) |
| No                                            | 295/969 | 30.4 | 1.0 | 1.0 |

Reported stress due to the spread of SARS-CoV-2

| Yes                                           | 254/746 | 34.0 | 1.587 (1.216–2.068) | 1.306 (0.892–1.911) |
| No                                            | 108/440 | 24.5 | 1.0 | 1.0 |

Table 2 cont.
alcohol on a typical drinking occasion during the pandemic
and the following factors: drinking alcohol 2 times a week and
more often before the pandemic (from OR: 2.587; 95% CI:
1.360–4.918 to OR: 12.021; 95% CI: 5.712–25.300),
consuming 3 or more alcoholic drinks on a typical drinking
occasion before the pandemic (for 3–6 drinks OR: 2.145;
95% CI: 1.270–3.623; for 7 or more drinks OR: 2.922; 95%
CI: 1.448–5.894) and increased frequency (once a week) of
heavy episodic drinking (OR: 2.380; 95% CI: 1.180–4.800)
(Table 3).

Table 3. Associations of sociodemographic factors, typical frequency and volume of alcohol use, consumption of unrecorded alcohol, negative consequences of the COVID-19 pandemic with the increase in the usual consumption (volume) of alcohol on a typical drinking occasion in the first months of the COVID-19 pandemic, 2020, (OR, 95% CI)

Factors associated with the increase in the frequency of heavy episodic drinking during the first months of the pandemic

Positive statistically significant associations were identified between the increase in the frequency of heavy episodic drinking during the pandemic and the following factors: drinking alcohol 2–3 times a week (OR: 2.756; 95% CI: 1.137–6.679) or more often before the pandemic (OR: 6.581; 95% CI: 2.585–16.749), having 7 or more drinks on a typical drinking occasion (OR: 2.202; 95% CI: 1.014–4.779) and heavy episodic drinking once a month or more often before the pandemic (OR: 2.561; 95% CI: 1.341–4.893 to OR: 2.647; 95% CI: 1.030–6.803) (Table 4). The odds of increase in the frequency of heavy episodic drinking were significantly more than two times higher among persons who reported severe negative consequences of the pandemic to their financial or professional situation (OR: 2.329; 95% CI: 1.001–5.428).
DISCUSSION

The associations revealed in our study are corroborated by other research works conducted in various countries during the first months of the pandemic. Specifically, in an Israeli study male sex was associated with increased consumption of beer and strong liquors [16], whereas in another study conducted in Canada male sex, stress, the feelings of isolation and hopelessness were associated with increased frequency of alcohol use in the first months of the pandemic [17]. In a UK study, stress caused by the pandemic was associated with the rise in hazardous drinking [18]. High levels of anxiety and stress caused by the pandemic led to the increase in alcohol use in Australia, France and Canada [17, 19, 20]. A few studies investigated changes in alcohol consumption in the general population unstratified by pandemic-related factors. Thus, a French publication reported an increase in total alcohol consumption during the lockdown [20]; by contrast, alcohol use in Greece and Spain during the lockdown was declining [21, 22]. However, in Greece and Spain the decline was less pronounced among stressed individuals and those with low or middle income. Compared to the prepandemic level, alcohol was purchased in larger quantities during the lockdown by Russian [23, 24] and UK households [25]. During the first months of the pandemic, retail alcohol sales were on the rise in the US [26]. A global study investigating changes in the availability and use of psychoactive drugs and alcohol during the pandemic reported a 71% increase in alcohol consumption across the world [27]. However, according to another large-scale study, alcohol consumption in the general population decreased in most European countries, including Russia, during the first months of the pandemic, mostly due to the reduction in the frequency of heavy episodic drinking [22].

Our study discovered a significant increase in 3 key parameters of alcohol consumption during the first months of the pandemic among those individuals who initially had consumed alcohol in larger quantities and more frequently. These key parameters include the frequency of drinking, the usual consumption (volume) of alcohol on a typical drinking occasion and the frequency of heavy episodic drinking. These findings suggest polarization of alcohol use, i.e. a situation when alcohol consumption grows among those who drink more at baseline and declines among those who typically drink less. This is consistent with the results of another online survey conducted in the general adult population of Russia [28]. The associations established in our study between the increase in the frequency of alcohol use/ heavy episodic drinking and such COVID-19-related factors as severe restrictions of everyday private life and the negative consequences of the pandemic to professional or financial situation uncover a new aspect or mechanism associated with stress which drives changes in drinking behaviors during the pandemic. Our findings go in line with the stress-associated patterns reported by the studies mentioned above and are consistent with previously reported changes in drinking behavior among Russians determined by certain sociodemographic characteristics, environmental factors and stress in times of socioeconomic and public health crises [29].

A potential limitation of this study might be the insufficient representativeness of the surveyed sample of online social media users in Russia. However, the size of this selection bias is likely small, because the survey was conducted among the users of social networking services highly popular in Russia and because the sociodemographic characteristics of the respondents were generally the same as those of the vast majority of online social media users in Russia. Besides, the consistency of the established patterns and associations with the results of other studies suggests that the probability of our results not being the consequence of selection bias is high. Another limitation of this study is that changes in alcohol consumption were assessed without differentiating between recorded and unrecorded alcohol. Therefore, additional analysis is needed to investigate changes in the consumption of unrecorded alcohol [30], considering its fairly high availability in Russia during the COVID-19 pandemic [31].

CONCLUSIONS

During the first months of the COVID-19 pandemic, over one-third of male and quarter of female online social media users in Russia increased the frequency of drinking. One in four men and one in five women increased their usual consumption (volume) of alcohol on a typical drinking occasion, and about one-third of men and women engaged in heavy episodic drinking more frequently than before the pandemic. Increased alcohol consumption during the first months of the pandemic was associated with male sex, younger age, severe restrictions imposed on everyday private life and severe negative consequences of the pandemic to the professional or financial situation. Further research is needed to investigate the possibility of implementing screening and brief interventions via online social media to prevent problems associated with alcohol use during large-scale epidemics and public health crises.
